Introduction
Head and Neck cancers are relatively common: squamous cell carcinoma of the head and neck (SCCHN) has a worldwide incidence of approximately 500,000 cases per annum [1]. Treatment is a combination of surgery, chemotherapy and radiotherapy (RT), devised to maximize the probability of eradicating the disease while retaining organ function [2-5]. Recent technical advances in RT include high-precision conformal techniques such as intensity-modulated radiation therapy (IMRT), which enable dose escalation to lesions without exceeding recommended exposure levels for organs at risk (OAR). However, these techniques require accurate anatomical information to contribute towards improving disease control.

High-resolution Magnetic Resonance Imaging (MRI) has increasingly been used to plan Head and Neck RT [6-10]. MRI and CT images are registered, combining the advantageous soft tissue contrast of MRI examinations and the required CT-based electron density. However, MR images are often distorted due to magnetic field inhomogeneity and non-uniform gradients [11-13], and the use of CT-MR fusion requires geometrically accurate MRI datasets. This article describes the equipment, protocols and techniques used in Head and Neck MRI at the Royal Marsden NHS Foundation Trust to ensure that the MRI examinations undertaken for RT planning purposes achieve the required geometric accuracy.

High resolution anatomical imaging in the radiotherapy planning position
At the Royal Marsden NHS Foundation Trust clinical Head and Neck MRI examinations for RT planning are undertaken at 1.5T in the 70 cm bore MAGNETOM Aera (Siemens Healthcare, Erlangen, Germany). Patients are scanned in the RT planning position using an appropriate head rest and thermoplastic shell immobilisation attached to an MRI-compatible headboard, modified to remain accurately positioned on the Aera patient couch. In addition to the elements of the posterior spine coil selected at the level of the lesion, a large flex-coil is also placed anteriorly, in line with the tumor, employing a custom-built plastic device to keep the coil curved, following the neck anatomy. This arrangement achieves a high signal-to-noise ratio, allows effective use of parallel imaging and keeps patient comfort in the RT planning position (Fig. 1).

The MRI protocol covers the primary tumor and neck lymph nodes with approximately isotropic T1-weighted sagittal 3D acquisition (TE 1.8 ms, TR 880 ms, 160 x 1 mm slices, 250 mm x 250 mm FOV, 256 x 256 image matrix). Images are acquired post contrast-agent injection (single dose). This dataset is subsequently registered with the RT planning CT examination, and for this reason its geometric integrity is checked periodically with a large linear test object, previously described [14], consisting of sets of straight tubes in three orthogonal directions. Figure 2 shows images of the test object without and with post-processing to correct image distortion. The 3D distortion correction built into the scanner software is essential for RT planning, and always used. The maximum displacement found within the volume encompassed by head and neck examinations is less than 1 mm. In addition, the imaging protocol employs a 500 Higsys pixel band-width, ensuring chemical shift related displacements in the readout direction remain under 0.5 mm.

Having characterized the geometric integrity of the protocol employed, it is also essential to characterize any further distortion associated with the distribution of magnetic susceptibility values within the subjects. In Head and Neck a large number of air-tissue interfaces in the vicinity of the tumors gives rise to localized magnetic field inhomogeneity, detrimental to the geometric integrity of the images. For this purpose, the field inhomogeneity in this region was estimated in five Head and Neck subjects. Transaxial gradient-echo images were acquired with fat and water in phase (TE values 4.76 and 9.53 ms), and the phase images were subtracted. The local field inhomogeneity was measured after phase unwrapping. Displacements associated with the airways were mostly under 0.5 mm with this sequence. Displacements only reach 1 mm in the vicinity of dental implants, and only very few pixels are affected.

Functional imaging
In addition to the clinical service providing anatomical images for RT planning, functional MRI is also employed to characterize lesions pre and post treatment and to investigate prediction of treatment response both at 1.5T (MAGNETOM Aera) and 3T (MAGNETOM Skyra). In RT planning, the ultimate aim of functional imaging techniques is to identify radioresistant disease and thus provide a biological target volume for dose boosting. Geometric accuracy is therefore essential to allow correct registration of functional MR images with anatomical MRI and CT datasets. In Head and Neck cancers, both diffusion-weighted imaging (DWI) and Dynamic Contrast-Enhanced (DCE) MRI have been explored [15-21].

Diffusion-weighted imaging with readout segmentation of long variable echo trains (RESOLVE); EPI-based DWI is sensitive to the mobility of water molecules and to their environment. In cancer, cell proliferation is often associated with an increase in cell density and in extracellular space tortuosity. This leads to lower values of the Apparent Diffusion Coefficient (ADC), compared to healthy tissues [22-23]. ADC values have been used for tumor detection, prediction and assessment of treatment response. EPI regions adjacent to air-tissue interfaces is known to suffer from poor geometric integrity [24]. Because this affects Head and Neck studies, strategies to reduce the echo-train length were sought. In addition to parallel imaging, the RESOLVE technique was also employed to acquire multi-shot DWI using a navigator signal to enable accurate multi-echo combinations. In Head and Neck studies, DWI with RESOLVE was employed, covering the volume of interest to identify restricted diffusion within primary lesions and affected lymph nodes.
Figure 3 compares DWI acquired without and with the RESOLVE technique for a Head subject, in a slice comprising air spaces. The clear improvement in geometric integrity achieved with RESOLVE DWI allows the registration of anatomical and functional images, thus allowing the use of DWI in RT planning for Head and Neck cancers (Fig. 4).

Dynamic contrast-enhanced MRI with CAIPIRINA-HIBE and TWIST view-sharing:

In dynamic contrast-enhanced (DCE)-MRI a series of 3D T1-weighted images is acquired to monitor contrast-agent uptake following an intravenous injection of contrast-agent. Using reference images, this technique can be quantitative and provide a dynamic calculation of T1 for each voxel. This enables pharmacokinetic modelling, providing information on tumor microcirculation, vascularity, blood volume and vessel permeability [25, 26]. This quantitative approach to DCE requires high temporal resolution to maintain accuracy. However, this conflicts with the need for high spatial resolution in RT planning applications.

The combination of flex-coil and spine coil elements has been used for DCE employing TWIST view-sharing and CAIPIRINA reconstruction to produce high resolution images (voxel size 2 mm isotropic × 44 slices, CAIPIRINA parameters: 2x2) with 2.5 s temporal resolution (TWIST: A = 33%, B = 33%, CAIPI: 2 x 2). An example of TWIST/CAIPIRINA DCE with a generous superior/inferior coverage to include both primary site and local involved lymph nodes is shown in Figure 5. Isotropic voxels allow for a good 3D delineation of a biological target volume. In addition, Dixon reconstruction of fat and water images also provides information on fat content within the imaged volume, which might be important in the context of tumor response to treatment. Figure 6 shows T1-weighted water-Dixon signal change after Gd injection for a given representative slice containing a primary tumour. Last frame shows Ktrans map within the region of interest.
