Working Together

The theme of the 99th Annual Meeting of the Radiological Society of North America is “The Power of Partnership.” Nowhere is this concept better exemplified than in the cooperation between academic medical centers and industry partners in the development and improvement of diagnostic imaging.

This issue of MAGNETOM Flash contains a wealth of examples of how such collaborations have advanced the discipline of MRI.

As the world population’s healthcare needs grow, so must diagnosis and disease management continue to advance. Diagnostic imaging plays an increasingly central role in detecting and characterizing disease, and guiding therapy. In particular, MRI remains a cornerstone of neurologic, orthopedic, oncologic, and cardiovascular imaging.

MRI has long had advantages in leveraging useful contrast mechanisms for visualization of anatomy and pathologic. This is well-demonstrated in articles describing visualization of diffusion-weighted imaging data [Doring et al. page 12], spectroscopic imaging of prostate cancer [Scheenen et al. page 16], susceptibility-weighted imaging [Ascencio et al. page 52], and quantitative myocardial relaxation mapping [Moon et al. page 104].

However, gone are the days when lengthy examinations producing inconsistent image quality were considered acceptable. In an atmosphere of rising cost and diminishing resources, all imaging is under pressure to demonstrate consistent examination quality, despite increasing use in challenging populations, such as the obese and those with diminished breath-holding capacity.

In their article on the New York University-Langone Medical Center experience using Compressed Sensing* methods [page 108 and 117], Mustafa Bashir et al. describe a six-minute comprehensive acute stroke protocol, combining brain structure imaging, functional measures including diffusion- and perfusion-weighted imaging, and MR angiography [page 44]. This “one-stop-shop” approach can facilitate rapid triage of appropriate patients to endovascular management while avoiding unnecessary, potentially dangerous, delays in diagnosis.

The broad availability of commercial wide-bore systems with high channel counts makes clinical MR imaging a reality in a larger portion of the population. Particularly in the United States, where over 35% of the population is obese [http://www.cdc.gov/obesity], high-quality imaging is now available to more patients than ever, with greater physical comfort. In addition to comfort, turnaround time is also considered an important measure of examination quality, and as a first-line diagnostic modality, MRI must provide rapid, definitive diagnosis in order for appropriate treatment to be rendered in a timely manner.

Finally, Mustafa R. Bashir, M.D., is an Assistant Professor of Radiology at Duke University Medical Center, Durham, USA. He joined the faculty at Duke in 2010, and serves as the Director of MRI and Director of Body MRI. In 2012, he was named the Medical Director of the Center for Advanced Magnetic Resonance Development, Duke Radiology’s MRI research and development facility. He has been awarded several industry research grants as principal investigator and serves as site imaging principal investigator on several NIH-funded grants. Dr. Bashir serves as a working group chair for the Liver Imaging Reporting and Data System (Li-RADS) committee for the American College of Radiology and is a site radiologist for the NIH-funded Non-Alcoholic Steatohepatitis Clinical Research Network. His clinical and research interests include abdominal MRI, liver imaging, quantitative imaging, and novel contrast mechanisms.

Introduction

Despite the tremendous developments that MR imaging has made over the last decades, one of the major limitations of conventional MRI is its pronounced sensitivity to motion, which requires strict immobility of the patient during the data acquisition. In clinical practice, however, suppression of motion is often not possible. As a consequence, MR images frequently show motion artifacts that appear as shifted object cephalic, which are usually known as ‘ghosting’ artifacts and which, depending on the artifact strength, can potentially obscure important diagnostic information. Ghosting artifacts pose a particular problem for abdominal-pelvic exams that need to be performed during suspended respiration. Because many patients struggle to adequately hold breath during the scan, the number of exams with suboptimal image quality is relatively high. This has impaired the acceptance of MRI as an imaging modality of choice in many abdominopelvic indications. Other widely utilized MRI applications such as heart and neck imaging are also often affected by motion-induced ghosting artifacts, e.g., if patients are anxious, or if they cannot suppress swallowing or coughing during the exam.

Radial k-space acquisition scheme

The high sensitivity to motion results from the data sampling strategy used in conventional MR imaging to spatially resolve the object. Conventional sequences acquire the data space (k-space) using a sampling scheme along parallel lines (Fig. 1A), which is usually referred to as ‘Cartesian’ sampling. The acquired parallel lines differ by a fixed difference in the signal phase, which is why the scheme is also called ‘phase encoding’ principle. However, if the object moves during the exam, phase offsets are created that disturb the phase-encoding scheme. In a simplified view, it can be thought of as a motion of the sampling lines, which causes gaps in the k-space coverage and results in aliasing artifacts along the phase-encoding direction from improper data sampling. Hence, the Cartesian geometry is inherently prone to motion-induced phase distortions. Even if navigation or triggering techniques are used to minimize phase inconsistencies within the acquired data, a certain amount of residual ghosting artifacts is almost always present.

The situation can be improved when changing the k-space acquisition to a different sampling geometry. One promising alternative is the ‘radial’ sampling scheme, which acquires the data along rotated spokes (Fig. 1B). Due to the overlap of the spokes in the center, gaps in the k-space coverage cannot occur if individual spokes are ‘jittered’ and, therefore, appearance of ghosting artifacts is not possible with this scheme. Furthermore, the overlap along the spokes reduces the averaging effect. Data inconsistencies can instead lead to ‘streak’ artifacts. However, in most cases these streaks have only a mild effect on the image quality, and they can easily be identified as artifacts due to their characteristic visual appearance (e.g., Fig. 3B). Because the artifacts appear mainly as ‘texture’ added to the underlying object, the likelihood that lesions get obscured is significantly lower than for the more dominant Cartesian ghosting artifacts.

Interestingly, although the advantages for clinical applications seem clear and although the idea of radial sampling has been known since the early days of MRI, the technique has not been widely employed in clinical practice so far. Radial sampling was first described by Lauterbur in his seminal MRI paper from 1973 [1]. However, because practical implementation required coping with a number of technical complexities, it was soon replaced by the Cartesian acquisition scheme which could be more easily and more robustly implemented on early MRI systems. These technical complexities include a more sophisticated image reconstruction, higher required homogeneity of the magnetic field, and the need for much more accurate and precise generation of time-averaging gradient fields. Consequently, radial sampling has only been used sporadically in research projects while clinically established techniques are currently almost exclusively based on the Cartesian scheme. Over the last several years, however, it has become possible to resolve the majority of issues that prevented a practical implementation of radial MRI, in part through improvements of the MR hardware designs and in part through improvements of the encoding/demodulation techniques. Therefore, it is now for the first time feasible to utilize radial acquisitions routinely on unmodified clinical MRI systems, with sufficient reliability and robustness for clinical applications and with image quality comparable to that of the conventional Cartesian scans.

Radial VIBE sequence

The Radial VIBE sequence is the first available works-in-progress sequence for Siemens MR systems that integrates these developments for volumetric acquisitions and provides radial k-space sampling in a fully seamless way, aimed at achieving higher robustness to motion and flow effects in daily practice. It is based on the conventional product VIBE sequence, which is an optimized T1-weighted 3D gradient echo sequence (3D FLASH) with various fat-saturation options. Radial sampling has been implemented using a 3D ‘stack-of-stars’ approach, which acquires the k-x, k-y plane along radial spokes and the k-z dimension with conventional sampling, resulting in cylindrical k-space coverage (see Fig. 2). This trajectory design enables use of time-efficient fat-saturation methods, such as Quick FatSat or SPIAIR, with minimal artifact strength, which is important as radial scans should be performed with fat suppression for most applications. Although Cartesian acquisition steps are employed along the k-z dimension, a high degree of motion robustness is achieved due to the use of an incoherent temporal acquisition order. The Radial VIBE sequence can be used on the full range of Siemens MR systems, including systems from the B-line generation (e.g., MAGNETOM Avanto, Trio, Verio) and D-line generation (e.g., MAGNETOM Skyra, Aera), and it can also be used on the Biograph mMR PET system as well as Siemens’ 7T** systems. Because the sequence does not require any modification of the MR hardware or reconstruction system, it can be deployed to installed systems and used clinically for fat-saturated T1-weighted exams as a motion-robust alternative to 3D GRE, VIBE, MPRAGE, or 2D TSE sequences.

Clinical applications and results

Over the last two years, the sequence has been tested extensively at NYU Langone Medical Center to evaluate the achievable image quality across various MR systems in daily routine applications. Radial VIBE scans were added to clinical protocols under IRB approval in more than 5000 patient exams and compared to established reference protocols. Several clinical studies have been performed or are ongoing that investigate the improvement in diagnostic accuracy resulting from the absence of ghosting artifacts.

Free-breathing abdominal imaging

A key application of the Radial VIBE sequence is imaging of the abdomen and/or pelvis before and after injection of a contrast medium, which is conventionally performed during suspended respiration. With Radial VIBE, it is possible to acquire the data during continued shallow breathing, which therefore can be the preferred exam strategy for patients who are unable to sustain the normally...
**Abdominopelvic exam of a sedated pediatric patient with Tuberous Sclerosis.** (6A) Because suspending respiration is not possible under deep sedation, conventional exams are affected by respiration artifacts. (6B) Radial VIBE provides significantly sharper images with improved spatial resolution, as visible from the small cysts in the kidneys.

**High-resolution abdominopelvic imaging**

The ability to acquire data during continued respiration also has advantages for the examination of patients with proper breath-hold capacity. With conventional Cartesian sequences, the achievable spatial resolution in abdominopelvic exams is limited by the amount of k-space data obtainable within typical breath-hold durations of less than 20 sec. Because Radial VIBE eliminates the need for breath holding, it is possible to sample data over several minutes and, thus, to increase the spatial resolution by a significant factor. Figure 4 demonstrates this possibility for an isotropic 1 mm high-resolution scan of the liver 20 min after injection of Gadoxetate Disodium, which provides clearly sharper visualization of the biliary duct compared to the corresponding Cartesian protocol. In figure 5, the achievable resolution improvement is shown for the case of MR enterography, which is another good candidate for Radial VIBE due to the higher overall robustness to the bowel motion.

**Pediatric imaging**

During the clinical evaluation phase, Radial VIBE demonstrated particular value for the application in pediatric patients. Pediatric exams are often conducted under general anesthesia or deep sedation, which makes active breath holding impossible. Therefore, conventional abdominopelvic scans are in most cases affected by respiration artifacts that impair the achievable effective resolution and diagnostic accuracy. Due to the inherent motion robustness, much sharper and crisper images are obtained with Radial VIBE, as evident from the depiction of small cysts in the kidneys of a patient with Tuberous Sclerosis shown in figure 6. A retrospective blinded-reader study of our case collection revealed that 8% of all lesions were only identified with Radial VIBE but missed in the corresponding Cartesian reference exams [3].

In young neonatal patients, sedation is usually avoided due to the higher risk of potential adverse effects. Imaging these patients is challenging because they often move spontaneously in the scanner. Also in this patient cohort Radial VIBE provides improved image quality and reliability, which is demonstrated in figure 7 for a brain exam of a 4-day-old patient, in this case compared to a Cartesian MPRAGE protocol.

*MR scanning has not been established as safe for imaging fetuses and infants less than two years of age. The responsible physician must evaluate the benefits of the MR examination compared to those of other imaging procedures.*
**Imaging of the neck and upper chest**

Although imaging of the head and neck region appears less critical at first glance, severe motion-related artifacts occur quite often in routine exams. Conventional neck protocols usually include slice-selective T1-weighted TSE sequences, which are especially sensitive to motion and flow. If patients are unable to suppress swallowing or coughing during the acquisition, images are rendered non-diagnostic. Furthermore, adequate examination of the upper chest region is often not possible because of drastic artifacts from respiration and strong blood flow in the proxim-ity of the heart. Radial VIBE exams provide a promising alternative for this application and are largely unaffected by swallowing, minor head movements, or flow, which is illustrated in figure 8. The sequence also maintains a convincing sensitivity to chest lesions in the presence of respiratory motion [4]. Because Radial VIBE scans are immune to ghosting artifacts, exams can be performed with high isotropic spatial resolution, which allows for retrospective reconstruction in multiple planes (MPR). In this way, it is possible to substitute multiple conventional slice-selective protocols in varying orientation with a single Radial VIBE high-resolution scan. A representative example is shown in figure 9.

**Imaging of the orbits, inner auditory canal, and full brain**

Finally, the sequence also offers improved sharpness and clarity for the examination of the orbits. When patients move the eyes or change the position of the eyelids during the exam, conventional protocols show a band of strong ghosting artifacts along the phase-encoding direction, which can make identifying pathologies a difficult task. Radial VIBE provides cleaner depiction of the optic nerves and improved suppression of intra- and extracranial fat [5]. Flow effects from surrounding larger blood vessels can lead to mild streak patterns but are less prominent than for most Cartesian protocols and can be additionally attenuated with the use of parallel saturation bands. The possibility to create high-resolution MPRs is another advantage of using Radial VIBE for this application, which is demonstrated in figure 10 for a patient with optic nerve sheath meningioma. In a similar way, the sequence can be applied for examinations of the inner auditory canal (IAC) or the full brain, in which a particularly high sharpness of vessel structures is achieved.

**Conclusion**

The large number of successful patient exams of various body parts conducted with Radial VIBE over the last two years demonstrates that radial sampling is now robust and reliable for routine use on standard clinical MR systems. Due to the higher resistance to patient motion and the absence of ghosting artifacts, improved image quality can be obtained in applications where motion-induced image artifacts are a common problem. In particular, the Radial VIBE sequence enables exams of the abdomen and upper chest during continued shallow respiration, which can be a significant advantage for patients that struggle to adequately hold breath. Furthermore, the sequence enables reconfiguring exam protocols towards higher spatial resolution and allows consolidating redundant acquisitions into MPR-capable isotropic scans. Because the sequence works robustly on existing MRI hardware, Radial VIBE has the potential to find broad application as motion-robust T1-weighted sequence alternative and will complement the spectrum of clinically established imaging protocols.

New Features of syngo MR D13 for Improved Whole-Body Diffusion-Weighted MRI

Thomas Doring; Ralph Strecker; Michael da Silva; Wilhelm Horger; Roberto Domingues; Leonardo Kayat Bittencourt; Romeu Domingues

CDPI and Multi-imagem (DASA). Rio de Janeiro, Brazil
Siemens Ltda, São Paulo, Brazil
Siemens Healthcare, Erlangen, Germany

Background

Whole-body diffusion-weighted imaging (WB-DWI) is gaining in clinical importance for oncological imaging. It has been shown to be a promising tool principally for tumor detection, tumor characterization, and therapy monitoring of bone metastases [1, 2]. The clinical implementation of WB-DWI aims for standardization of the acquisition protocol. For this reason, further improvements of data acquisition, analysis and display of the results are requested.

The recently launched new software version syngo MR D13 provides several new features for WB-DWI such as variable averaging of the b-values, inline composing, and a Bias Field Correction (BiFiC) filter in order to overcome previously existing limitations such as long acquisition times, mis-registration between, and intensity inhomogeneities across image stations.

New features in syngo MR D13 b-value specific averaging

One limitation of the broader clinical usability is the long acquisition time of over 25 minutes for head-to-pelvis WB-DWI MRI. For more efficient scanning the new feature b-value specific averaging was developed: This allows us to set the number of averages (NEX) for each b-value individually. The current product protocol uses a b-value of 50 with NEX 2, and a b-value of 800 with NEX 5, resulting in a reduction of scan time of 30%, when compared to the previously used NEX 5 for all b-values (Fig. 1). A similar image quality can be achieved for lower b-value images with lower NEX with almost no impact on the signal-to-noise ratio (SNR) for the calculated ADC.

New composing mode diffusion

An inline composing filter can be activated within the diffusion sequence of syngo MR D13 on the diffusion taskcard of the sequence (Fig. 2). The composing itself is a fully automatic process and creates for each b-value a continuous stack of composed images as an individual new series. Similarly a new series for the optional calculated b-value images is generated. Depending on the local shim situation the frequency differences between neighboring stations can lead to discontinuities of anatomical structures like the ‘broken-spine’ artifact. During the composing step a correction is applied showing a much smoother transition of local anatomy (Fig. 2).

In older software versions (syngo MR D11) composing had to be done manually within the syngo 3D taskcard by dragging and dropping all trace-weighted series at once with no possibility to correct for any discontinuities in the anatomy. The new inline composing feature significantly improves the acquisition workflow of the radiologist as it allows to load the single composed series to syngo 3D for the generation of the 3D reformatted maximum intensity projection (MIP) images.

Bias Field Correction (BiFiC) filter

The BiFiC filter as a homomorphic filter aims to normalize inhomogeneities in image intensities from multi-station measurements such as whole-spine imaging. After completing the inline composing step the filter is automatically applied to the composed 3D continuous image stack and saved as the new composed series. The strength of the filter (weak, medium, strong) can be set within the diffusion task card (Fig. 2, arrow).

Fig. 1. By checking the Inline Composing box in the diffusion taskcard of the sequence the automatic composing modus is activated. The strength of the BiFiC filter can be set to weak, medium or strong (red arrows).

4A

Fig. 2. In the Diffusion taskcard it is now possible to select the number of averages for each b-value individually (Here: b50 NEX 2, b800 NEX 5, red arrows).

4B

By checking the Inline Composing box in the diffusion taskcard of the sequence the automatic composing modus is activated. The strength of the BiFiC filter can be set to weak, medium or strong (red arrows).

64-year-old female patient, after surgery, with endometrial stromal sarcoma, that has evolved with bony metastases. Acquisition parameters: 1.7T MAGNETOM Aera, echoplanar imaging diffusion sequence with fat suppression (STIR). TR 1410 ms, TE 79 ms, TI 180 ms, 4 stations, 50 slices with 5 mm slice thickness, no gap, voxel size 1.7 × 1.7 × 5 mm³, b50 with 2 and b800 with 5 averages. (3A) b800 manually composed images within the syngo 3D tool shows the artifact in the neck shoulder transition where the stations are joined (arrows). (3B) The new inline composing feature demonstrates significantly better composing of the neck and shoulder transition.
Conclusion

The new features within the product sequence of syngo MR D13 improve the image quality of whole-body DWI when compared to older software versions. The new inline composing filter, in particular, shows good results in the neck-shoulder transition compared to the previously manual technique in syngo MR D11 that was not able to recover discontinuities in the spine. Improvements in the clinical workflow are also addressed.

Introduction
Prostate cancer is the second leading cause of cancer related death in Western countries [1]. The prevalence of the disease is very high, but many men diagnosed with the disease will die from unrelated causes. This is because prostate cancer very often is a disease of old age that grows slowly. Common treatment for prostate cancer in clinical practice involves radical resection of the entire gland or radiotherapy with a dose distributed over the whole organ. Provided that the cancer has not metastasized, these therapies are curative, though concern over their side effects has led to patients and their doctors delaying this treatment and, instead, entering into active surveillance or watchful waiting programs. In order for patients to safely forgo curative treatment, it is essential to characterize the disease, that are appropriate for active surveillance or watchful waiting programs. In order for patients to safely forgo curative treatment, it is essential to characterize their disease: to determine that it is sufficiently benign that growth will be slow and metastasis improbable. Selecting these patients, with low risk disease, that are appropriate for active surveillance requires accurate diagnosis of not just the presence of tumor, but how aggressive it is: i.e. how fast it is growing and how likely it is to metastasise to the lymphatic system.

Radiologists can read the different imaging modalities to decide the location, size and potential malignancy of the tumor which are all indicators of its metastatic potential. Acquiring and reporting imaging data in this way is known as multiparametric (mp) MRI. mpMRI is the only mpMRI methodology that acquires data from molecules other than water [19]. A three dimensional (3D) 1H MRSI data set consists of a grid of spatial locations throughout the prostate (see Fig. 1) called voxels. For each voxel a spectrum is available. Each spectrum consists of a number of peaks on a frequency axis, corresponding to resonances from protons with a certain chemical shift in different molecules. The size of a peak at a certain frequency (chemical shift) corresponds to the amount of the metabolite present in the voxel. In this way MRSI measures the bio-chemicals in regions of tissue in vivo without the need for any external contrast agent or invasive procedures. Examples of spectra from two voxels, acquired at a magnetic field strength of 3 Tesla (3T), are given in figure 1B, C, which clearly shows the differing profiles that are characteristic of benign prostate tissue and its tumors.

Important metabolites in prostate MRSI
The initial papers on in vivo prostate MRSI were performed at a magnetic field strength of 1.5T [3-5], and three assignments were provided for the observed resonances: choline, creatine and citrate (Fig. 2). The small number of these assignments reflected the simplicity of the spectrum, which contained two groups of resonances: one in the region of 3.3 to 3 ppm, which will be referred to as the choline-creatinine region, and another at 2.55–2.75 ppm, which shall be called the citrate group. These assignments related to what were believed to be the strongest metabolite resonances. People should be aware however, that the assignments are representative of multiple similar molecules. The choline assignment reflects the methyl resonances from multiple compounds containing a choline group (Fig. 4): choline, phosphocholine and glycerophosphocholine. Similarly, creatine refers to both creatine and phosphocreatine. In between the choline and creatine signals another group of resonances are present: the polyamines (mainly spermine and spermidine). The citrate resonances are from citrate only but can have a complicated shape, although in vivo at 1.5T they give the appearance of a single peak. Nowadays a magnetic field strength of 3T is used more and more for prostate spectroscopic imaging, which gives opportunities to better resolve the choline, polyamines, creatine resonances, but also changes the shape of the citrate signal. Larger choline signals are associated with tumor in nearly all cancers [6]. High choline signals are interpreted as being evidence of rapid proliferative growth and, more directly, the increased membrane turnover required for cell division. Membranes contain phospholipids: phosphatidylcholine and phosphatidyl ethanolamine, which are synthesised by a metabolic pathway involving choline-containing metabolites known as the Kennedy pathway. It is in the synthesis and catabolism of these products, upregulated in proliferative tumor growth, that causes the increase in these signals.

The large amplitude of citrate resonances observed in prostate tissue is due to an altered metabolism particularly to this gland. Prostate tissue accumulates high concentrations of zinc ions which inhibit mitochondrialaconitase, leading to a build up of citrate in the prostate’s epithelial cells [7]. This citrate is further sequestered into the ductal spaces of the prostate as...
The introduction of a metabolite ratio

To transform the described changes in choline and citrate signals between benign (high citrate) and tumorous tissue (low citrate, high choline) into a marker for prostate cancer, the metabolite ratio was introduced (3-5). The signal intensities of the different spectral peaks were quantified by simple integration of the two groups of resonances (the choline-citrate region and the citrate group), and the results were expressed as a ratio of the two. This gave the choline plus creatine over citrate ratio (abbreviated to **Cho/Ci** [4]) or its inverse (with citrate as the numerator, [3, 5]). With choline in the numerator and citrate in the denominator, it became a positive biomarker for the presence of cancer.

Acquiring the MRSI data sets

As the prostate is embedded in lipid tissue, and lipids can cause very strong unwanted resonance artefacts in prostate spectra, the pulse sequence to acquire proton spectra is equipped with five properties to keep lipid signals out and retain optimal signals-of-interest in the whole prostate [9].

1. Localization of the signal with slice-selective pulses. The point resolved spectroscopy sequence (PRESS) is a combination of one slice selective excitation pulse and two slice selective refocusing pulses leading to an echo at the desired echo time. The three slices are orthogonal, producing an echo of the volume-of-interest (crossing of three slices) only.

2. Weighted acquisition and filtering. Proton MRSI data sets are acquired using a phase encoding technique where the gradients across spatial dimensions are varied with each repeat of the pulse sequence. By using weighted averaging of these phase encoding steps (smaller gradient steps are averaged more often than larger gradient steps) and adjusted filtering of the noise in these weighted steps, the resulting shape of a voxel after the mathematical translation of the signal into an image (Fourier Transform) that only touch upon water and lipid signals. Together with strong crushing gradients, signals from water and lipids are suppressed.

3. Frequency-selective water and lipid suppression. The pulse sequence has two additional refocusing pulses

4. Outer volume suppression. Around the prostate, slice-selective pulses can be positioned to suppress all signals in the selected slabs. These slices can be positioned quite close to the prostate, even inside the PRESS-selected volume-of-interest.

5. Long echo time. To accommodate all localization and frequency selective pulses, the echo time of 1H MRSI of the prostate is around 120 ms at 1.5T and 145 ms at 3T. At longer echo times, lipid signals decay due to their short T2 relaxation time.

The prostate is small enough (< 75 cubic centimetres) to allow a 3D 1H MRSI data set to be acquired, with complete organ coverage within 10 minutes of acquisition time. The nominal voxel size is usually around 6 x 6 x 6 mm, which after filtering as described above results in a true voxel size of 0.63 cm³.

Spectral patterns

Due to multiple different protons in the molecule, a single metabolite can have multiple resonances. If interactions exist between protons within a metabolite, the shape of a spectral peak can be complicated. A resonance group of protons that has a mixture of positive and negative parts is said to have a dispersion component in its shape, a symmetrical-positive peak is referred to as an absorption shape. Choline and creatine resonances appear as simple peaks (singlets), thereby displacing the prostatic fluid.

The relative contribution of each of these two physiological changes, whether we are observing tumor formation and malignant progression or a histological change in tumor invasion of ductal structure, is not yet known. It is, however, clear that there are two diminishing effects on the overall level of citrate metabolite and tumor cell density with some evidence to support a similar correlation with the aggressiveness of the tumor as well [8].
although they very often cannot be separated from each other as they overlap within in vivo spectral line - widths. The structure of citrate, given in figure 4, results in protons at two different chemical shifts, with coupling between each proton and one other (a strongly coupled spin sys - tem). The spectral shape of these protons depends on their exact chemical shift, the coupling constant between them, the pulse sequence timing and the magnetic field strength. At an echo time of 10 ms at 1.5T (and a very short delay between excitation and first 180° degree refocusing pulse), the spec - tral peaks of citrate are close to a positive absorption mode. The spec - tral shape consists mainly of an inner doublet with small side lobes on the outer wings. Together with line broadening the citrate protons quite closely resemble a single, somewhat broadened peak. The small side lobes around this peak are hardly detect - able over the spectral noise in vivo. At 3T with an echo time of 145 ms (examples given in Fig. 1), the nega - tive dispersion components of the citrate shape cannot be ignored. Its side lobes are very large and reveal also some negative compo - nents [10]. Therefore the area under the curve, the integral, is substantially smaller at 3T than at 1.5T. Because of its complicated shape, it is essen - tial at 3T to incorporate this shape in quantification of the signal.

Signal quantification by integration or metabolite fitting

The size of the peaks of the individ - ual resonances represent the amount of the metabolite present in the voxel. Integration provides a simple method to quantify the spectra, as long as all signals have an absorption shape. Although it cannot discriminate between overlapping resonances, as long as overlapping signals (choline and creatine) are summed in a ratio this does not matter. With clear separ - ation between citrate resonances and the choline-creatine region, the C/C ratio can be calculated. How - ever, as pointed out earlier, the spec - tral shape of citrate is not straight - forward, and ignoring the small satellites at 1.5T, or simply integrat - ing the large dispersion parts of the signal at 3T, would inevitably lead to underestimation of the total citrate signal intensity. An alternative is to fit the spectra with models of the citrate resonances with their expected shape. The shape can either be measured, using a solution of citrate placed in the MRI system and a spec - trum acquired with the same sequence as the in vivo data, or it can be calcu - lated using a quantum mechanical simulation (Fig. 3). By this process of spectral fitting, models of each metabo - lite’s spectral peaks are fit to the total spectrum and the intensities of each fitted model are calculated. A linear combination of the metabolite models is found by the fitting routine such that

$$\text{Data} = C_1 \cdot \text{choline model} + C_2 \cdot \text{creatine model} + C_3 \cdot \text{citrate model}$$

The coefficients $C_i$ give the relative concentrations of the individual metabolites.

When fitting with symg sync via, the ratio of a fit to a spectral peak can be expressed in two ways: as an integral value, which describes the area under the fitted spectral peak, or as a relative concentration (incorporating the num - ber of protons in the corresponding peak) of the metabolite, called the scale factor (SF) of the metabolite.

As noted earlier, the integral value of citrate is different for 1.5 vs. 3 Tesla due to the different spectral patterns and would also change if pulse sequence timing other than standard would be used. If the scale factor is multiplied with the number of resonat - ing protons ($\varphi_i$), it represents the intensity of a signal, in relation to the integral value of a pure singlet of one resonating proton in absorption mode.

We call this entity pseudo integral, which is calculated as $\varphi_i$

$$\text{pseudo integral (Metabolite) = } \varphi_i \cdot \text{SF (Metabolite)}.$$  

For citrate this pseudo integral is per - haps best described as the numerical integration of the peak (all negative intensity turned positive) of the citrate spectral shape, ignoring signal cancel - lations of absorption and dispersion parts of the shape. The spectral fits are shown for the two spectra in figure 5 with model spectra of the three metabolites choline, creat - ine and citrate. It can be seen from these spectra that the relative ampli - tudes of the metabolites vary between the benign and the tumor spectrum.

As expected, the benign spectrum has a higher citrate amplitude while the tumor has a greater choline amplitude, relative to the other metabolites. Com - bined in the C/C ratio, the positive biomarker for the presence of tumor in the prostate is calculated.

Depending on the used quantification (spectral integration without fitting (a), fitted relative concentrations (b) or pseudo integrals (c)) the C/C ratio can be calculated by:

(a) $\text{Integral(Choline)} + \text{Integral(Creatine)}$

(b) $\text{SF(Choline)} + \text{SF(Creatine)} / \text{SF(Citrate)}$

(c) $\text{3SF(Choline)} + \text{3SF(Creatine)} / 4 \text{SF(Citrate)}$, respectively.

The numbers in the last equation correspond to the number of protons of the different signals. Generally, use of the pseudo integral ratio is strongly preferred, as it is least sensi - tive to large variations in individual metabolite fits in overlapping signals (choline and creatine). Note (again) that this pseudo integral ratio does not aim to provide a ratio of absolute metabolite concentrations, as this is very difficult with overlapping metabolite signals, partially saturated metabolite signals due to short T1 effects, and variation in signal attenuation due to the use of a long echo time (T2 effects).

Now, what could be the effect on the ratio if further metabolites are included in the fitting? Could even polyamines be incorporated in the analysis? After separate fitting, the main focus of the analysis could just be on choline and citrate, which have opposite changes in intensity with cancer, to make a simpler and potentially more sensitive choline/ citrate ratio. Various metabolite ratios have been proposed [12, 13], and there is certainly value in using choline over creatine as a secondary marker of tumor malignancy that can give complementary information to the C/C ratio [14-16]. However, any of these interpretations are limited by how well the individual metabolite resonances can be resolved. At 3T the choline, polyamines and creatine resonances all overlap (Figs. 1 and 5). In practice this lack of resolution in the spectrum translates to errors in the model fit. Moreover, the citrate metabolite can be overestimated at the expense of another. For example a choline over citrate ratio could be underestimated if the polyamines fit was overestimated and accounted for some of the true choline signal.

While acquisition and fitting methods are being actively researched to improve the presentation of quantification of these metabolites, it is more reli - able to stick to the pseudo-integral C/C ratio.

Once reliably calculated, the C/C ratio combines the essence of the observable spectroscopic data into a single quantity that can be displayed on an image (Fig. 6), combining the key information into a simple to read form for radiological reporting.

Published values of the ratios for tumor and benign tissue, which are calculated in a similar way to the spectrum via fitting, are listed in table 1.

Future perspective of MRSI for prostate cancer

The C/C ratio is the most used method for interpreting 1H MRSI data of prostate and prostate cancer. It remains, essentially, the integral of the choline-creatine region divided by the citrate region, a simple combi - nation of the metabolite information in a single-value marker that is sensi - tive to the presence of tumor. The use of areas under the resonances in the ratio has the implication that the absolute value of this biomarker is largely dependent on the acquisition sequence used. Any change in field strength, the pulses or pulse timings will change resonance amplitude and shape due to T1 and T2 relaxations and the scalar couplings of especially citrate. Values of the ratio quoted in the literature for tumor or benign tissues depend strongly on how the

Abstract

The emerging development in modern radiotherapy planning (RTP) requires sophisticated imaging modalities. RTP for high precision requires exact delineation of the tumor, but this is currently the weakest link in the whole RTP process [1]. Therefore, Magnetic resonance imaging (MRI) is of increasing interest in radiotherapy treatment planning because it has a superior soft tissue contrast, making it possible to define tumors and surrounding healthy organs with greater accuracy. The way to use MRI in radiotherapy can be different. The MRI datasets can be used as secondary images to support the tumor delineation, which is routinely in use in many radiotherapy departments. Two other methods of MRI guidance in the RTP process are until now only research projects, but interest in them is increasing. The first method is to use MRI data as the primary and only image dataset and the second is the application of the MRI data as reference dataset for a so-called ‘MRI-guided radiotherapy in hybrid systems’ (Linear Accelerator (Linac) or Cobalt RT units combined with MRI). For all cases it is essential to create the MRI datasets in the radiotherapy treatment position. For this reason the CIVCO Indexed Patient Positioning System (IPPS) MRI-Overlay was introduced and tested with our Siemens MAGNETOM Aera MRI Scanner.

Introduction

Although computed tomography (CT) images are the current gold standard in radiotherapy planning, MRI becomes more and more interesting. Whilst CT has limitations in accuracy concerning the visualization of boundaries between tumor and surrounding healthy organs, MRI can overcome these problems by yielding superior soft tissue contrast. Currently there are three different possible strategies by which MRI can help to improve radiotherapy treatment planning:

- The MRI datasets can be used as secondary images for treatment planning. These MRI images can be used to delineate the tumor and the surrounding organs, whilst the CT images – the primary planning data – are necessary to calculate the 3D dose distribution. The two image datasets have to be co-registered thoroughly to ensure that the anatomy correlates (see for example [2]). The registration accuracy strongly depends on the MRI scan position. Harvey et al. [3] and Brunt et al. [4] have shown that it is indispensable for the MRI dataset to be created in the treatment position which is primarily defined by the CT scan.

- The MRI dataset can also be used as the only dataset. Because of the lack of electron density information, which is required for dosimetric calculations, bulk densities have to be applied to the MRI images. For this purpose the different anatomic regions like bone, lung, air cavities and soft tissue have to be overestimated with the physical densities. With this method it is possible to achieve dose calculation results quite similar to the calculation in the CT dataset in the head and neck region [5, 6] as well as in the pelvic region [7]. The advantage of this method is that by avoiding the CT scan you save some time and money. In this case it is necessary for the treatment position to be determined during the MRI scan, hence the MRI scanner has to be equipped with the same positioning and immobilization tools as the Linac. Further problems to overcome are the evaluation and correction of possible image distortions and the determination of accurate bulk densities.

- After the RTP process there are a lot of remaining uncertainties such as set-up errors, motion of the target structures and during the treatment changes of the tumor volume and shrinking. This problem can be overcome with the so-called image-guided radiotherapy (IGRT). IGRT involves a periodical verification (weekly or more frequent) of tumor position and size with appropriate imaging systems. It is evident that IGRT is only as good as the accuracy with which the target structures can be defined. For this reason some groups try to develop hybrid systems, where a Linac or a cobalt treatment unit is combined with an MRI scanner for a so-called ‘MR-guided radiotherapy’ [8–10]. Again, MR-guided radiotherapy can only be successful when the reference MRI dataset has been created in the treatment position.

In any of the above three cases, where MRI can be helpful to improve the accuracy of radiotherapy, it is strongly advised that one has a robust and reproducible patient positioning and immobilization system, mainly at the MRI scanner, which is used for MR-guided RTP. Siemens provides with the CIVCO IPPS MRI-Overlay a suitable solution. In our clinic we have introduced and tested this MRI-overlay, especially for patients with tumors in the pelvis and for brain tumors and metastasis.

Method

Our 1.5T MAGNETOM Aera system (Siemens Healthcare, Erlangen, Germany) is located in the radiology department and can temporarily be used by the staff of the radiotherapy department. For the purpose of MR-guided RTP we have equipped the MAGNETOM Aera with the CIVCO IPPS MRI-Overlay. This overlay enables the fixation of positioning and immobilization tools necessary for radiotherapy treatments. For our purpose we have used an MR compatible mask system for head and neck cases and vacuum cushions for patients with diseases in the pelvic region both from Medical Intelligence (Elekta, Schwabmünchen, Germany). These tools can all be fixed with so-called index bars (Figs. 4, 12) at the MRI-Overlay. These index bars are custom designed for our purpose by Innovative Technologies Völp (IT-V, Innsbruck, Austria) for the MRI-Overlay and for use in the high field magnetic environment. For the correct positioning of the patients, the laser system Doroado 3 (LAP, Luneburg, Germany) was additionally installed in the MRI room. The preliminary modifications and the patient positioning is described in the following for two cases.

The first case describes the procedure for a patient with a head tumor. The first step is the removal of the standard cushion of the MRI couch and the mounting of the MRI-Overlay (Figs. 1–3). One index bar is necessary to fix the mask system on the overlay (Figs. 4, 5) to avoid movements and rotations during the scan. Because the standard head coil set cannot be used with the mask system, two flex coils (Flex4 Large) have to be prepared (Figs. 6–8). In figure 8 one can see, that the correct head angle could be adjusted. Now the patient is placed on the overlay and in the mask system. The patient’s head can be immobilized with the real and proper mask made from thermoplastic material called CAST (Medical Intelligence, Elekta, Schwabmünchen, Germany)
Two flex coils (Flex4 Large) are prepared. 

4. The flex coils have to be positioned partly under the mask system, because the whole head of the patient should be covered.

5. It is possible to adjust the head angle in an appropriate and reproducible position that is comfortable for the patient.

6. Now the patient is immobilized using a custom-made mask made from thermoplastic material.

7. The flex coils are closed with hook-and-loop tapes.

8. The patient is ready for the scan.

A second vacuum cushion is attached to the overlay (Figs. 16, 17). This can be done with hook-and-loop tapes (Fig. 18). Now the patient set-up is completed and the MRI scan can be started (Fig. 19).

Two examples are shown in the following pictures. In Fig. 20 you can see a brain tumor in two corresponding slices. The left picture shows the CT slice and the right picture shows the corresponding MRI slice obtained with a T1-weighted sequence with contrast agent. It is clear to see that tumor boundary is much more pronounced in the MRI image. Figure 21 shows the same slices with structures created by the radiotherapists. It is also helpful to create some control structures, such as brain and ventricles, to check the accuracy of the registration. Figures 22 and 23 give an example of a patient with prostate cancer. In this case the MRI images on the right

are acquired using a T2-weighted TrueFISP sequence. The boundary of the prostate and the differentiation between prostate and rectum is much more easier to define in the MRI images. The control structures in this case are the femoral heads. For the head scans we normally use 3 sequences, a T1w SE with contrast agent, a T2w TSE and a FLAIR sequence. For the pelvis scans we normally use a T2w SPACE, a T2w TrueFISP and a T2w TSE sequence. The coordinate system should be the same for all sequences, that means same slices and same field-of-view. Hence one can use the same registration parameters for all sequences.

References

Conclusion and outlook
We can now look back over a period of two years working with the CIVKO IPPS MRI-Overlay. Our experience is very promising. The modifications on the table of the MRI scanner are very easy and can be executed and finished in only a couple of minutes. The procedure is well accepted by the radiologic technologists. To date, we have scanned more than 100 radiotherapy patients, mainly with diseases in the pelvis (rectum and prostate cancer) and in the head (brain tumors and metastasis). So far we have only used MRI dataset as a secondary image dataset. The co-registration with the CT datasets is now much easier because we have nearly identical transversal slices in both image datasets.

As a conclusion we can say that we are very happy with the options we have to create MRI scans in the treatment positions. It has been demonstrated that the MRI dataset is now much more helpful in the radiotherapy planning process. We should mention the need for a quality assurance program to take possible image distortions into consideration. Our next step is to install such a program, which involves the testing of suitable phantoms. A further step will be to assess whether we can use MRI datasets alone for RTP.

Introduction

Turbo Spin-Echo sequences at 1.5T can generate noise at over 100dB, inside the bore [1–3]. This noise is equivalent to standing 5 meters away from a jackhammer [3], and would be even louder on higher field systems. Despite the use of ear-protective equipment, reducing the Sound Pressure Level (SPL) generated by these standard clinical sequences could noticeably improve patient comfort [4]. MRI pulse sequences mostly generate acoustic noise because of rapidly varying gradient waveforms: The resulting Lorentz forces applied on the gradient coils vibrate [5]. To circumvent this issue, several hardware solutions have been proposed. For example, the whole gradient coil can be enclosed in a vacuum chamber [6–8], or gradient field rotation can be performed mechanically [9]. While these solutions achieve significant noise reduction for all types of sequences, they can noticeably increase manufacturing cost, and can even decrease gradient efficiency. Mechanical and acoustic balanced designs of gradient coil systems including windings performing active acoustic control have also been considered and investigated [10, 11].

Modifying and/or optimizing pulse sequences can also reduce acoustic noise effectively. One such solution is to time the ramping up and ramping down of the gradient waveforms so that the induced scanner vibrations cancel each other out [12]. Another approach is to use lower gradient amplitude and slew rates of the gradient waveforms [13]. By low-pass filtering the gradient, vibration frequencies for which the acoustic response of the gradient coil is high can be avoided. Elaborate redsgins of gradient waveforms coupled with parallel imaging have demonstrated further reduction of acoustic noise in Echo Planar Imaging (EPI) [14, 15]. The reduction was achieved by counterbalancing lengthened gradient waveforms with increased acquisition speed, thereby reducing acoustic noise without increasing acquisition time while maintaining inter-echo spacing, only at cost of signal-to-noise ratio (SNR). By extending such principles to other generally-used standard clinical MR sequences, this article demonstrates that with minor SNR reductions (≤ 10%), effective reduction in acoustic noise can be further achieved without noticeable degrade of diagnostic information or imaging time, as well as without sacrificing gradient efficiency.

Two types of modifications in a T2-weighted Turbo Spin-Echo (TSE) sequence were investigated for acoustic noise reduction: First by solely modifying the gradient waveforms and second by additionally using GRAPPA at a reduction factor of two (R=2)\(^*\). Comparative SPL measurements at the bore were performed between standard TSE, quiet TSE (qTSE)\(^*\) and quiet TSE with GRAPPA (qTSE-G)\(^*\). A statistical analysis of comparative scores from a reader’s study was conducted.

Methods

The gradient waveforms of the TSE sequence were optimized with an automatic gradient optimization algorithm that extends any slope duration to its maximum and reduces the number of slopes to their minimum. For instance, with minor changes in protocols, spoiling and crusher gradient lobes are replaced by long rising or descending slopes, while maintaining the crusher moment unchanged. To keep the same total acquisition time, the reduction of the gradient slew rate is constrained by the fixed inter-echo spacing. The decreased slew rate of readout gradient will slightly reduce readout sampling time (Fig. 1). In consequence, the readout bandwidth (BW) increases slightly, with a tradeoff between reduction of SPL and SNR loss.

\(^*\)WIP, the product is currently under development and is not for sale in the US and other countries. Its future availability cannot be ensured.

Mean and standard deviation, 95% confidence interval, and p-value of the scores given by each radiologist to the different types of image volume pairs after self-bias correction. Positive score shows preference of the right volume over the left volume, on a -10 to +10 scale.

In-vivo studies were performed on a 3 T MAGNETOM Verio MRI scanner (Siemens Healthcare, Erlangen, Germany) with a 12-channel head coil with patients admitted for head examination. Informed consent was obtained from the volunteer before the start of the study in accordance with IRB protocol. A total of 10 different patient scan sessions were performed, each comparing standard TSE image volumes with qTSE and qTSE-G images. The image resolution (192 x 256 matrix), number of slices (26), slice thickness (5 mm) and slice orientation were kept identical throughout the 10 different acquisitions.

To measure acoustic noise level LAEQ (Equivalent Continuous Sound Level in A-weighting) with 30 seconds average and peak values, a professional device, 2238 Mediator sound level meter (Bruel & Kjaer GmbH, Bremen, Germany) was used, which was placed inside the bore at head position.

The background noise is mainly generated by the cold-head pump and the ventilation among other sources. To evaluate the image quality, a total of 7 image-volume-pairs were assembled from each of the 10 patient datasets. The first 2 pairs compared qTSE with TSE volumes, alternatively with qTSE with the left and TSE on the right. Similarly, another 2 pairs compared qTSE-G with TSE volumes in both left-right orders randomly. Finally, 3 pairs were assembled with the same volume on the left and right, which consist of TSE vs. TSE, qTSE vs. TSE, qTSE-G vs. qTSE-G volumes, respectively.

All 70 volume pairs were presented in the same random order to 3 trained radiologists blinded to the acquisition technique, who were asked the following question: “On a scale from -10 to +10, how much better is the image quality of the volume on the right compared to the volume on the left, with a positive score indicating superiority of the right volume, and 0 representing no difference in quality between left and right?”. The graphical user interface used for the reading allowed user-navigation through the paired-volume slices, and simultaneous image windowing of the 2 displayed images.

To avoid possible left-right bias, the average of the qTSE vs. TSE score and the TSE vs. qTSE score multiplied by -1 was then calculated for each reader’s reading on each patient. The average of the corrected scores across readers was then computed for each patient. Corrected scores were calculated in the same way for the qTSE-G vs. TSE comparison. One-sample t-tests were used to test whether the mean average reader scores differed from zero, and 95% confidence intervals (CI) for the mean scores were also calculated. One-sample t-tests and CI were also carried out using each reader’s scores separately. A reader’s average rating of these three self-comparisons using images from each patient were averaged, and then the three reader averages were averaged for each patient. A t-test was used to test whether the average of the reader ratings across patients differed from zero. One-sample t-tests and CI were also carried out for each reader separately.

Results

The respective average and peak SPL in [dB] measurements for standard TSE, qTSE and qTSE-G protocols are listed in Table 1. The achieved reduction of average SPL for qTSE and qTSE-G was 10 dB, and near 20 dB, (30 seconds average), respectively.

Discussion

Optimizing the gradient waveforms alone with a 10% increase in bandwidth achieves an 11 dB, SPL reduction (Table 1), with little cost to image quality (Fig. 3). These results are in accordance with [16] though here the measurements were made directly at the bore. This cost might be more noticeable with lower SNR systems, however in this configuration, no statistically significant difference in image quality was observed (Table 2), making gradient redesign a viable solution to make TSE sequences quieter.

With additional use of Parallel Imaging, the modified quiet TSE sequence allows on average a 20 dB, reduction in SPL (Table 1). The modified sequence had an effect on in image quality separately with the highest reader scores for standard TSE images over qTSE-G images was .24 ±1 (p<0.0001, Table 2), and the 95% confidence interval places its true value between +1.8 and +3. However it should be noted that this change in image quality is to be expected as Parallel Imaging was used. In compensation, the reduction of acoustic noise was highly effective: the SPL at the bore of the standard TSE sequence was 39.5 dB, higher than the background noise, compared to 19.7 dB, for the modified sequence.

Conclusion

In comparison with standard MR sequences, gradient wave modifications in TSE sequence coupled with Parallel Imaging can achieve over a factor 10 of acoustic noise reduction, yielding an improved patient comfort with nearly identical diagnostic information and imaging time. Without any hardware modifications or upgrade, both proposals described in this article, qTSE and qTSE-G can be easily implemented on a conventional MRI system for routine clinical applications. In addition, scanning on a high field system with multiple channel coils, such as the 32-channel head coil, provides more flexibility to make MRI scanning quieter.

Quiet T1-weighted 3D Imaging of the Central Nervous System Using PETRA

Masahiro Ida, M.D.1; Matthew Nielsen, M.A.2

1Dept. of Radiology, Tokyo Metropolitan Ebara Hospital, Tokyo, Japan
2Research & Collaboration Dept., Healthcare Sector, Siemens Japan K.K., Tokyo, Japan

Introduction

Nearly all MRI sequences in routine clinical use employ rapidly varying magnetic field gradients that generate considerable acoustic noise, one of the primary causes of patient discomfort and restlessness [1]. Eliminating such noise would provide additional comfort for all patients, and may provide particular advantages for patients with psychiatric*, dementia and certain psychiatric diseases who tend to have difficulty relaxing or remaining still during MR examinations.

Ultra-short echo time sequences such as zero-TE [2], SWIFT [3] and PETRA [4] require only limited gradient activity and allow for inaudible 3D scanning. However, due to ultra-short TEs, the image contrast is given by the steady state and is limited to the range of PD-to-T1-weighting unless pre-pulses are used [5]. Similar to the MPRA * sequence [6-8], stronger T1-weighting can be generated by applying an inversion pre-pulse before every n-th repetition in the PETRA* sequence. A study has shown that this quiet inversion-prepared PETRA sequence is capable of T1-weighting comparable to that of MPRA * when measured in the same time and with the same spatial resolution [1].

In this article, examples of quiet inversion-prepared PETRA images are compared with conventional 3D T1-weighted images (MPRAGE or 3D-FLASH) from the same patients. All of the examples were obtained during brain examinations, and all but one of the examples employed contrast enhancement.

PETRA sequence principles and noise reduction

In the PETRA sequence, gradients are already on and stable at a certain amplitude before the excitation pulse. Due to the fact that the gradient strength on each axis is altered only slightly during each repetition, the gradient strength on each axis is altered only slightly meaning that the required slew rate is extremely low (e.g., < 5 T/m/s with...
PETRA [1]. The resulting deformation and vibration of the gradient coil is negligible and produces almost no audible sound. Completely unrelated to the gradients however, transmit-mode-to-receive-mode switching (and vice versa) in receive-only RF coils produces some noise [1], while PETRA is essentially inaudible when used with transmit-and-receive RF coils. The acoustic noise levels generated by PETRA and MPRAGE on a MAGNETOM Trio A Tim System (3T) were measured using a sound-pressure meter with A-weighting. PETRA afforded a reduction in acoustic noise of more than 25 dB, with both the 12-channel head matrix coil and the 32-channel head coil. Since both coils were receive-only, an even greater reduction can be expected with transmit-and-receive coils.

PETRA versus routine sequence image comparisons

While MR angiography (MRA) is undoubtedly the most commonly used 3D sequence in brain MRI exams, other 3D sequences are used in certain circumstances at Tokyo Metropolitan Ebara Hospital. The most common one is contrast-enhanced (CE) 3D FLASH which is employed for the following indications because of its high spatial resolution and short echo time:

1. To precisely diagnose head & neck tumors, pre- & post-operatively (with Quick FatSat),
2. To inspect blood pools (AVM, thrombosis, aneurysm, dissection), and
3. To detect cranial nerve inflammation.

The second most common 3D scan other than MRA is CE MPRAGE which is employed to diagnose intracranial brain tumors. Among those, the most common indication is screening for intracranial metastases.

MR imaging was performed on a 3 Tesla MAGNETOM Trio A Tim System. PETRA was added to routine patient exams that included either MPRAGE or 3D-FLASH. The parameters of the three sequences are shown in Table 1. The center of k-space for MPRAGE (scan time: 5 min 56 sec) was acquired approximately 6 to 11 minutes after contrast media administration, while the center of k-space for PETRA was acquired approximately 3 minutes later than that of MPRAGE. 9 to 14 minutes after contrast media administration. PETRA acquires the central portion of k-space first (in a pointwise fashion as shown in figure 1) before acquiring the rest of 3D k-space with radial trajectories. A previous study showed that for enhancing intracranial lesions with a diameter of 5 mm or larger, enhancement reached a plateau in less than 10 minutes and lasted until at least 20 minutes after contrast media injection [9]. Thus, the 3 minute difference in the acquisition of k = 0 between MPRAGE and PETRA would not result in differing lesion enhancement, and any difference in lesion enhancement can be taken as primarily due to sequence characteristics.

Protocols provided with the PETRA sequence were designed to parallel the contrast and spatial resolution (0.9 to 1.0 mm cubic voxels) typically available with MPRAGE. Therefore, initial work with PETRA at our hospital focused on comparisons with MPRAGE. One of the protocols placed the priority on signal-to-noise ratio (SNR) (TI 900 ms), and one placed the priority on contrast-to-noise ratio (CNR) (TI 500 ms, for higher contrast between gray matter (GM) and white matter (WM)). The scans of both PETRA protocols were adjusted such that they were similar to that of the MPRAGE protocol used in patient exams. In a pilot study, volunteers and patients were scanned with both PETRA protocols and with MPRAGE. The SNR on PETRA images with TI 900 ms was visibly higher than on MPRAGE images, while PETRA images with TI 500 ms provided more GM-to-WM contrast than necessary for CE studies in the opinion of one radiologist (MI). A decision was made that some of the SNR could be ‘traded’ for tissue CNR, and an intermediate TI of 700 ms was chosen for further CE studies. Statistical comparisons of contrast enhancement and SNR between PETRA and MPRAGE were performed (that study is under review for publication in a peer-reviewed journal).

PETRA was also compared with 3D-FLASH while remaining conscious of the fact that, compared to the PETRA implementation discussed in this article, 3D-FLASH was capable of higher spatial resolution.

*Repetition time of RF excitation pulses, which for MPRAGE is displayed on the MR console as ‘Echo spacing’.�
Contrast-enhanced screening for brain metastases was indicated for a 70-year-old female who had lung cancer. A small metastasis was detected in the suprapendymal zone of the pons (arrows) on both sequences.

Contrast-enhanced screening for brain metastases was indicated for a 69-year-old male who had lung cancer. A small metastasis was detected in the corticomedullary junction of the left parietal lobe on both sequences.

Contrast-enhanced images of glioblastoma in a 56-year-old female patient (not proven histologically).

Contrast-enhanced images of glioblastoma in a 33-year-old male patient.

Contrast-enhanced screening for brain metastases was indicated for a 69-year-old male who had lung cancer. A small metastasis was detected in the corticomedullary junction of the left parietal lobe on both sequences.
Comparisons of PETRA and 3D-FLASH

Comparisons between PETRA and 3D-FLASH are shown in figures 9 through 12. While the acquired spatial resolution was higher for 3D-FLASH (0.6 × 0.6 × 1.0 mm³) than for PETRA, the clinical findings were not affected in these cases. PETRA had a voxel size of 0.993 mm³ (Figs. 9, 10) or 0.803 mm³ (Figs. 11, 12).

General clinical observations
Susceptibility-related artifacts and flow voids were absent on PETRA images, while signal from cortical bone was observed. All three observations can be attributed to the ultra short TE. The absence of susceptibility-related artifacts should allow PETRA to detect sinusitis or tumors within the paranasal sinuses which tend to be highly distorted on 3D gradient-echo-based sequences such as MPRAGE and 3D-FLASH. Positive signal from bone may be useful in cases of head trauma for detecting fractures and in surgical planning and follow-up. While CT is normally used for this purpose in adults, its use is highly restricted in children. PETRA may be able to readily provide 3D bone images even for children, or to provide more frequent follow-ups after surgery in adults.

The masticator space and the paranasal space at the skull base tended to appear ‘dirty’ or ‘messy’ on PETRA images, but this was not the result of an artifact or distortion. Rather, this appearance was caused by strong venous enhancement due to the absence of flow voids. Also on PETRA, the dura mater as well as the mucosa in the paranasal sinuses exhibited contrast enhancement, and the enhancement of the dura was uniform in most cases. This was likely due to blood pool enhancement in capillary arteries which are dense in those tissues, in combination with the absence of flow voids as a result the ultra-short TE. Such enhancement did not appear on MPRAGE and 3D-FLASH images. The uniform enhancement of the dura would prevent the use of PETRA for the detection of dural inflammation, dural metastasis, intracranial hypotension or other causes of local dural enhancement. Nevertheless, many other applications of 3D T1-weighted imaging exist such as those presented in the current article.

Finally, PETRA demonstrated excellent fat suppression which would allow the sequence to be employed, not only for the diagnosis of extracranial, orbital and paranasal tumors including bone-marrow metastases of the calvaria and cranial base.

Contrast-enhanced screening for brain metastases was indicated for a 63-year-old male. A ring-enhancing lesion was detected in the left temporal lobe on both sequences. (8A) CE MPRAGE; (8B) fat-suppressed CE PETRA.

Contrast-enhanced images of dilated, abnormal medullary veins representing developmental venous anomaly (red arrows) in a 47-year-old female patient. Yellow arrows: Small blood pool enhancement in the combined cavernous malformation.

Blue arrows: T1 shortening caused by methemoglobin. (9A) CE 3D-FLASH with a voxel size of 0.6 × 0.6 × 1.0 mm³. (9B) CE PETRA (TI 700 ms) with a voxel size of (0.99 mm)³.

Contrast-enhanced images of combined cavernous malformation and developmental venous anomaly in a 47-year-old female patient. (10A) CE 3D-FLASH with a voxel size of 0.6 × 0.6 × 1.0 mm³. (10B) CE PETRA (TI 700 ms) with a voxel size of (0.99 mm)³.

Flow voids are absent due to the ultra-short TE causing the venous malformation to appear more prominently. Developmental venous malformation was apparent in the same patient, again appearing more prominently on PETRA due to the ultra-short TE and lack of flow voids. (10C) CE 3D-FLASH. (10D) CE PETRA.
Contrast-enhanced images of small vestibular schwannoma (arrows) localized in the right acoustic canal of a 67-year-old female patient. (11A) CE 3D FLASH with a voxel size of 0.6 × 0.6 × 1.0 mm³. (11B) CE PETRA (TI 900 ms) with a voxel size of (0.80 mm)³.

Normal optic nerves and paranasal sinuses in a 74-year-old male patient. (12A) 3D FLASH with a voxel size of 0.6 × 0.6 × 1.0 mm³. (12B) PETRA (TI 900 ms) with a voxel size of (0.80 mm)³. The septi of the paranasal sinuses are depicted clearly in the ethmoid sinuses due to the absence of susceptibility-induced artifacts.

Normal paranasal sinuses in the same patient. (12C) 3D FLASH. (12D) PETRA. Notice the absence of susceptibility-induced artifacts in the paranasal sinus.

Conclusion
The acoustic noise (A-weighted) generated by PETRA was drastically lower than that of MPRAGE, while contrast-enhancement and image quality were similar between the two sequences, and clinical findings did not differ, as shown in several examples. In comparisons of PETRA with 3D-FLASH, although the latter provided a higher spatial resolution, again clinical findings did not differ. Quieter MRI examinations will be more comfortable for all patients, and may have particular advantages for pediatric, dementia and certain psychiatric patients.

Acute MR Stroke Protocol in Six Minutes

Kambiz Nael; Rihan Khan; Kevin Johnson; Diego Martin
University of Arizona, Department of Medical Imaging, Tucson, AZ, USA

Background
Stroke is a common and serious disorder, with an annual incidence of approximately 795,000. Based on American Heart Association statistics update in 2010, approximately 610,000 of these are first attacks, and 185,000 are recurrent attacks. On average, every 40 seconds, someone in the United States has a stroke with an estimated mortality rate of 5.5%, claiming approximately 1 of every 18 deaths in the United States [1].

Neuromaging plays a central role in the evaluation of patients with acute ischemic stroke (AIS). With improved technology over the last decade, imaging now provides information beyond the mere presence or absence of intracranial hemorrhage including tissue viability, site of occlusion, and collateral status. While computed tomography (CT) is the most widely available and faster imaging modality, some comprehensive stroke centers favor streamlined MR protocols over CT in the acute stroke setting due to the higher specificity and superior tissue characterization afforded by MRI. The success of CT in initial evaluation of AIS is due, in part, to fast acquisition time, widespread availability and ease of interpretation in the emergency setting. The introduction of multi-slice technology has dramatically increased the speed and simplicity of CT techniques and has set a high standard for alternative imaging techniques. A comprehensive CT stroke algorithm including parenchymal imaging (non-contrast head CT), CT angiography (CTA), and perfusion/penumbral imaging by CT perfusion can now be acquired and processed in less than 10 minutes [5, 6].

MRI has been demonstrated to be more sensitive for the detection of acute ischemia and more specific for delineation of infarction core volume when compared to CT [7, 8]. However, due to longer acquisition time and limited availability, it has been mainly used in large institutions and comprehensive stroke centers. A comprehensive MR protocol including parenchymal imaging, MRA and MR perfusion can now be obtained in the order of 20 minutes as demonstrated in several clinical trials [9–13]. If MRI is to compete with CT for evaluation of acute stroke, there is need for further improvements in acquisition speed.

In this article we describe our modified acute stroke MRI protocol that can be obtained in approximately 6 minutes rivaling that of any comprehensive acute stroke CT protocol. We describe the technical aspects and review a few clinical examples based on our preliminary results.

92-year-old man with sudden onset of right-sided weakness and aphasia presented to our emergency department after receiving IV-tPA at an outside institution. The acute stroke protocol was performed after 9 hours from the onset in our institution and selective images are shown.

In this article we describe our modified acute stroke MRI protocol that can be obtained in approximately 6 minutes rivaling that of any comprehensive acute stroke CT protocol. We describe the technical aspects and review a few clinical examples based on our preliminary results.
Technical consideration

A comprehensive MR stroke protocol has three essential components:
1) Parenchymal imaging that identifies the presence and size of an irreversibly infarcted core and determines the presence of hemorrhage;
2) MR angiogram to determine the presence of proximal arterial occlusion and/or intravascular thrombus that can be treated with thrombolysis or thrombectomy;
3) Perfusion imaging to determine the presence of hypoperfused tissue at risk for subsequent infarction if adequate perfusion is not restored.

Below we describe each of these components in detail and explain how recent technical advances can be used to enhance the performance of the different aspects of acute stroke imaging.

1. Parenchymal imaging

This encompasses three parts:
1) DWI (diffusion-weighted imaging) that can detect ischemic tissue within minutes of its occurrence and has emerged as the most sensitive and specific imaging technique for acute ischemia, far beyond NECT or any other type of MRI sequences [14].
2) FLAIR that helps to age the infarction and permits the detection of subtle subacute or old hemorrhage;
3) GRE to detect parenchymal hemorrhage with comparable accuracy for the acute intraparenchymal hemorrhage to CT [15].

Both FLAIR and GRE images have been used to detect intraarterial clot with variable sensitivity and specificity [16, 17].

Introduction of fast imaging techniques such as parallel acquisition [18] and EPI [19, 20] has significantly enhanced the performance of MR imaging in terms of acquisition speed. The main advantage of EPI, as in the case of DWI imaging, is rapid acquisition time, which is made possible by rapid gradient switching which permits the acquisition of all frequency and phase encoding steps during a single pulse cycle. The addition of parallel imaging can further enhance the acquisition speed and may also serve to mitigate the geometric distortion and susceptibility artifacts commonly associated with long echo-train sequences such as EPI [21, 22]. If their potential is realized, the application of EPI and parallel imaging techniques to the FLAIR and GRE sequences can result in reduction of image acquisition time of the entire brain to less than a minute, a three-fold reduction in scan time over conventional imaging [23, 24].

2. MR Angiogram

An important aspect of the workup of patients with AIS is the imaging of both the intracranial and extracranial vasculature. Precise imaging of the vascular tree is required during the initial assessment of patients with acute stroke to accurately detect the site of arterial disease, which in turn can be crucial in determining the type of acute therapy they are given. Intravenous thrombolysis has been shown to be more effective in small distal vessels than in the large vessels [25]. Larger vessel occlusion may be more effectively treated with intra-arterial thrombolysis or clot retrieval devices while associated with fewer complications [26, 27]. In addition, MRA of the extracranial circulation (neck arteries) is essential to establish the mechanism of ischemia and to prevent subsequent episodes of Extracranial tandem stenoses with plaque involving the carotid or vertebral arteries can be the source of disease that triggers an acute stroke. Time-of-flight MRA (TOF-MRA) has been traditionally used in routine stroke protocols to evaluate the status of neck and brain arteries. Despite its promising results [28], TOF-MRA has significant disadvantages including spin saturation and phase dispersion due to slow or turbulent flow [29, 30]. This can result in overestimation of arterial stenosis and increase false positive rates, usually due to slow flow distal to a subocclusive thrombus or clot.

Most importantly the acquisition time usually is long, typically lasting 5–7 minutes.

The general consensus is that contrast-enhanced MR angiography (CE-MRA) provides more accurate imaging of extracranial vessel morphology and of the degree of stenosis than TOF-MRA techniques [31–33]. However, CE-MRA has not been widely incorporated into acute stroke protocols for several reasons. First, CE-MRA has lower spatial resolution relative to TOF-MRA, since the competing requirements of coverage and acquisition speed generally force a compromise in spatial resolution for CE-MRA [34]. A second potential limitation to incorporation of CE-MRA into clinical stroke protocols is related to the requirement of an extra contrast dose, which would be in addition to the intravenous contrast bolus normally utilized for perfusion imaging. With introduction of high performance MR scanners and recent advances in fast imaging tools such as parallel acquisition (GRAPPA) [18], high matrices can now be spread out over a large field-of-view encompassing the entire head and neck, resulting in acquisitions with substantially shorter acquisition times on the order of 20 seconds [35, 36].

3. MR Perfusion

MR perfusion imaging has been used broadly in the identification of potentially salvageable tissue to determine the best treatment strategy in patients with acute ischemic stroke. Although the concept of perfusion-diffusion mismatch remains controversial [37, 38], it has been used with some success to identify patients who may respond favorably to revascularization therapies in several clinical trials [12, 13, 39].

Faster image acquisition combined with higher signal-to-noise ratio (SNR) resulting from the use of gadoxitinum contrast agents has helped dynamic susceptibility contrast (DSC) perfusion become a more robust and widely accepted technique in comparison to arterial spin labeling (ASL) to identify the presence of perfusion abnormalities in patients with AIS. A refined MR stroke protocol that can combine both CE-MRA and DSC-perfusion with improved acquisition time and diagnostic image quality as previously suggested [47, 48] may have important therapeutic and prognostic implications in the management of patients with acute stroke. Higher inherent SNR of higher magnetic fields such as 3T with improved multi-coil technology has resulted in acquisition of low dose CE-MRA of the supra-aortica arteries with contrast dose as low as 8 ml [40, 41]. A modified 2-phase contrast injection scheme [46] can be used to perform both CE-MRA and DSC perfusion imaging, without the need for additional contrast. The influence of both contrast dose reduction on DSC perfusion has been evaluated by several investigators [42, 43] and contrast dose as low as 0.05 mmol/kg has been used to perform DSC perfusion with promising results [44, 45].

Advances in MR technology including hardware and software, faster gradient performance of MR scanners, improved sequence design and fast imaging tools such as EPI and parallel...
acquisition have promised the potential for a fast but comprehen- sive diagnostic imaging protocol that can be performed in approximately 6 min- utes rivaling those of CT protocols. Next we review our stroke protocol in terms of image acquisition and sequence parameters and show some of the clinical examples that were performed at our institution.

How we do it

TOGETHER WE MOVE FORWARD IN THE FIGHT AGAINST CANCER

When two leading companies join forces in the fight against cancer, it broadens the realm of what’s possible. That’s why Varian and Siemens have partnered. Siemens’ advanced diagnostic imaging capabilities combined with Varian’s powerful delivery systems and treatment planning tools give even more of an edge in the pursuit of our common goal: to EnVision better cancer care. Together we offer more personalized treatment and expanded care options that aid you in making the best possible decisions for your patients—with confidence. By gathering our strengths, we have the energy and vision to better help healthcare professionals detect, diagnose and treat cancer while paving the way for the future of cancer care.

Susceptibility-Weighted Imaging: Initial Experience

José Luis Ascencio L1, Tania Isabel Ruíz Z.2

1 Escanografía Neurologica, Medellin, Colombia
2 Universidad CES, Radiology, Medellín, Antioquia, Colombia

Introduction

Susceptibility-weighted imaging (SWI) is a sequence that utilizes a phenomenon in which the phase and change in the local magnetic field of the tissues are proportional to one another, provided the echo time is constant [1]. It uses magnitude and phase images, as well as a summation of these in a three-dimensional gradient echo sequence with flow compensation [2]. It offers high sensitivity for visualizing calcium, non-heme iron (ferritin) and hemoglobin degradation products (deoxy-hemoglobin and hemosiderin) [3, 4].

Initial experience

By means of a series of cases we will illustrate the clinical usefulness of SWI with certain neurological conditions. The studies reviewed were performed in the Neurological Scanography Magnetic Resonance Imaging Service using a Siemens MAGNETOM ESSENZA 1.5 Tesla MRI unit with the following settings: TR 49 ms, TE 40 ms, FA 15°, number of slices 60, slice thickness 2 mm, acquisition matrix 256 × 157.

Susceptibility-weighted imaging takes advantage of the loss of signal intensity created by alterations in a homogeneous magnetic field; these disturbances can be caused by several different paramagnetic or diamagnetic substances. The loss of signal intensity in the T2*-weighted sequence is a result of the difference in the precession rate of the spins [5]. The susceptibility image is obtained during the acquisition process by combining the magnitude and phase of the images. Routine MR images are magnitude images where the signal’s intensity is converted to a gray scale. Phase information is obtained at the same time, but is generally ignored. A filter is applied to the phase image (High-pass Hamming Window Filter) on a 64 × 64 matrix to reduce aliasing artifacts. A new phase mask is created which, when added to the magnitude image, creates the susceptibility image. In order to obtain a better interpretation, minimum intensity projections (minIP) are used [6]. During post-processing the phase contrast image is filtered to reduce undesirable low spatial frequency components, leaving the high frequency field variations. The phase mask created can be ‘positive’ or ‘negative’. The phase mask is multiplied using the original magnitude image to produce images that maximize the negative intensity of the mineralization of the parenchyma. Minimum intensity projection (usually from 2 to 4 slices) is used to display the processed data [1].

The method is highly sensitive for purposes of visualizing venous circulation, blood products and iron content, and is also useful for evaluating the vascularization of tumors and for identifying brain tissue that has been compromised by a stroke, vascular dementia or trauma, and can also be used in functional imaging [1, 4, 7–9] (Fig. 1).

Hemorrhage

Oxyhemoglobin, formed by the binding of an oxygen and an iron atom contained in the heme group, is a diamagnetic substance. When the oxygen is released from the iron atom it forms deoxyhemoglobin, which is paramagnetic because of its unpaired electrons. Metahemoglobin is produced when deoxyhemoglobin oxidizes, making it less stable; in this state there is little susceptibility effect and thus it is easily visualized in T1w images. Hemosiderin is the final product of the degradation of hemoglobin when it degrades within phagocytic cells, and is a highly paramagnetic [3, 4, 10] substance. Diamagnetic substances produce a weak local magnetic field, while paramagnetics generate a stronger magnetic field that leads to a signal decrease and therefore a signal reduction in the T2* sequence [4]. The ferritin produced by different metabolic processes also has paramagnetic characteristics and is associated with Parkinson’s disease, Huntington’s disease and Alzheimer’s disease [9–11].

Trauma

In the detection of diffuse axonal damage, this approach is more sensitive than conventional imaging for detecting microhemorrhages in the deep and subcortical white matter, which can be obscured in computed tomography (CT) scans [12, 13]. It is three to six times more sensitive than gradient echo images for detecting the number, size, and location of the lesions associated with this clinical status of the patient [1, 13–16]. It is equally useful in detecting brainstem lesions, subarachnoid and intraventricular hemorrhage, as well as other types of hemorrhagic lesions of different origins [17] (Fig. 2).

Calcifications

Calcium is also diamagnetic and can lead to changes in the susceptibility image [12, 16]. SWI differentiates iron from calcium based on their diamagnetic or paramagnetic characteristics in the filtered-phase image. Calcium appears brilliant in this latter image, while the hemorrhage and its derivative products have low signal intensity. This differentiation is important when dealing with neurodegenerative and metabolic diseases, trauma, and tumors [12, 18].

Vascular malformations

Venous blood causes non-homogeneity in the magnetic field due to the paramagnetic effect of the deoxygenated blood due to T2* reduction, depending on the oxygen saturation, the hematocrit and the condition of the erythrocytes; thus, the deoxyhemoglobin present in venous blood allows for the visualization of the latter [4] as well as the phase difference between the vessels and surrounding structures [19]. The susceptibility image provides contrast similar to that of a functional image (BOLD blood oxygen level-dependent).

SWI is more sensitive in the detection of vascular structures that are hidden to T2* and low-flow malformations that are not detected by MR angiography, such as venous development malformations, telangiectasias and cavernomas, as well as vascular abnormalities and calcifications related to Sturge-Weber Syndrome, since it is not affected by flow velocity or direction [20–24]. In dural sinus thrombosis they show venous stasis and collateral flow, as well as early detection of venous hypertension before infarcts or hemorrhages occur [7, 8, 19] (Figs. 3–5).
Venous development anomaly. (3A) Axial gradient echo; anomaly not visible. (3B) Axial contrast-enhanced image shows right frontal venous development anomaly that is more evident in the susceptibility image (3C).

Left frontal cavernoma. (4A) Axial proton density-weighted image; (4B) miniP SWI.

Left parietal arteriovenous malformation. (5A) Axial PDw show serpiginous images with absence of flow signal. (5B) miniP SWI. (5C) MIP TOF shows the AVM and the cortical drainage vein.

Metastatic melanoma. (7A) T2w axial; large mass displacing the midline, with major edema and hypointense zone due to hemorrhage in the medial portion. (7B) Magnitude image. (7C) MIP SWI shows a greater hemorrhagic component of the mass, on the contralateral side, as well as intraventricular hemorrhaging.

Hemorrhagic metathesis. (6A) T1w axial gadolinium-enhanced. (6B) T2w axial show a left parietal mass with heterogeneous enhancement, perilesional edema and mass effect on the lateral ventricles. (6C) MIP SWI shows hypervascularity and hemorrhage in the interior of the mass.

Brain tumors
This approach provides information that supplements T1 with contrast for detecting margins, internal architecture, hemorrhage and vascularization of a tumor that are not visible with conventional sequences. This aids in differentiating between a recurring tumor and post-operative changes. The use of susceptibility imaging before and after the administration of gadolinium can differentiate areas of enhancement of the vessels. Because of its suppression of cerebrospinal fluid, it enhances contrast between edema and normal tissue, similarly to what is provided by FLAIR, thus facilitating the detection of space-occupying lesions [4, 7, 25] (Figs. 6–8).

Oligodendroglioma. (8A) T1w axial gadolinium shows mass with enhanced foci and a cystic component. (8B) MIP SWI right parietal hypervascular mass with increased relative flow (8C).
Cerebrovascular disease

The susceptibility image can be used together with diffusion images to detect the hypoperfused region, the presence of hemorrhaging within the infarct (which could affect the treatment), detect acute thrombus and predict the likelihood of hemorrhagic transformation and hemorrhagic complications [30]. After thrombolysis treatment, as well as microbleeding due to amyloid angiopathy and lacunar infarcts in patients with hypertensive encephalopathy [19, 26-28] (Figs. 9, 10).

Neurodegenerative illnesses

Certain disorders, such as Parkinson’s disease, Huntington’s disease, Alzheimer’s, multiple sclerosis and amyotrophic lateral sclerosis (Lou Gheri’s Disease) present with abnormal iron deposition, which can be determined and quantified using susceptibility imaging [11, 30-33]. SWI can show chronic demyelinating plaques with iron depostions that are hidden in conventional sequences, as the iron content makes the lesions more visible. It also allows detecting the iron content of the nuclei of deep gray matter that can be also observed in patients with multiple sclerosis, as well as the perivascular distribution of the demyelinating lesions [30].

Curve Fitting of the Lipid-Lactate Range in an MR Spectrum: Some Useful Tips

Jamie Ho Xiu Mei; Helmut Rumpel

Department of Diagnostic Radiology, Singapore General Hospital, Singapore

Purpose
In the course of a neurological spectroscopic application, questions about the lipid-lactate signals often occur: How can we accurately interpret an asymmetric pattern with ‘humps’ and partially inverted signals? How can we recognise some fundamental patterns in order to differentiate between, for example, an early membrane degradation and necrosis? In addition, questions always arise about the proportion of lipid and lactate in an overlapping pattern. This article offers some hints to curve fitting of the lipid-lactate range and to avoid incorrect or misleading labelling of the peaks of an MR spectrum.

Background
The lipids are a large and diverse group of naturally occurring molecules with various functions, from storing energy to being components of membranes. They include miscellaneous subgroups, such as triglycerides of subcutaneous fat or bone marrow and glycerophospholipids of membranes. In Fig. 1. They have in common fatty acids comprising four different proton groups: olefinic protons at 5.5 ppm, allylic protons and protons adjacent to the carboxyl group at 2.0 ppm, aliphatic methylene groups (main peak) at 1.3 ppm, and the terminal methyl group at 0.9 ppm. However, their T2 values differ according to whether the fatty acids are part of triglycerides or cell membranes. Unlike glycerophospholipids, fatty acids in membranes are embedded in the interior of the membrane resulting in efficient spin-spin interactions, thus revealing short T2 values. As such, even in short TE spectra, signals from intact membranes are hardly visible, whereas the freely tumbling fatty acids in triglycerides and also the less restricted ‘fragments’ of fatty acids from membrane degradation produce strong signals due to a longer T2. In drawing a comparison with an iceberg, proton groups at 5.3 ppm, allylic protons and protons of membranes namely those of methyl-, methylene-groups, choline, and myo-inositol, are MR-invisible unless they ‘surface’ due to degradation processes (Fig. 2). For example, depending on the grade of degradation of membranes in brain tumours, the MR signals of the said membrane fragments are raised in a characteristic way [1].

Line curve fitting in the NUMARIS software
Within the NUMARIS software, line curve fitting is done in the frequency domain [2]. It is the last of the post-processing steps. Provided that the phase correction is optimal, the adequate line curve fitting protocol has to be selected out of a set of three ‘customised’ protocols, namely: 1. lipid signal only, e.g. TE 30 lip 2. lactate signal only, e.g. TE 30 loc 3. lactate and lipid signals e.g. TE 30 lip - loc

They are easily derived from the Siemens protocol (CSI or SVS) TE 30 using the interactive post-processing environment and adding new peak parameters and peak restrictions (see User Manual). The lipid-containing protocols fit both the lipid_1,3 and the lipid_0.9 peaks with parameters as shown in figure 3. An analogous set of protocols shall be customised for TE 135.

How do we identify lipids and lactate?
- Lipid-only peak (Fig. 3A): Here, the assignment method is straightforward. Firstly, we look at the line width of the peaks. Their full width at half maximum is reciprocally proportional to T2. As a rule of thumb, T2 of lipids is shorter than that of lactate, and thus the lipid peak is broader. Secondly, one can also look at the symmetry of the peak (whether it has a symmetrical Gaussian / Lorentzian shape). Thirdly, lipids should appear as two peaks. Their relative intensities may vary depending on the stage of degradation (Fig. 4).

How do we identify lipids and lactate?
- Lactate-only peak (Fig. 3A): The scalar coupling constant J IS and phase dependency of the lactate signal, S ~ |cos (JIS TE)| can be used as a kind of lactate editing: a doublet signal of 7 Hz and a 180° degree phase shift at TE 135 ms. In contrast to the lipid peak, the lactate peak reveals a sharp doublet pattern, or at least it appears foreshadowed.

Lipid-lactate peak (Fig. 3A): In the case of lipid-lactate overlapping, this approach of Lorentzian-Gaussian curve fitting will be inaccurate in differentiating between lipid and lactate proportions, because the best fit is driven by the method of least squares rather than taking pre-knowledge of different shapes into account. In fact the operator will identify asymmetric patterns (showing a hump on one side) or if they partially invert on TE 135 ms spectra (Fig. 3B). Representative cases are shown in figures 5 and 6.
How I do it

In *syngo* via the approach of curve fitting in the time domain has been chosen [3]. It is based on PIRMA [4] using the basis set of metabolic time signals of brain metabolites together with published values of chemical shifts and coupling constants. The delineation of a lactate-lipid overlap is based on free induction decays (FIDs), in which the distinct T2 values make the segmentation more accurate. Figure 7 depicts two examples:

a) with a clearly visible hump at half maximum of the Lip_1.3 peak, and
b) with only an adumbrated hump (arrow).

It demonstrates that delineating highly non-uniform signal compositions is possible with only one protocol for all cases. The protocol can be easily linked together by selecting the appropriate lactate and lipid templates as shown in figure 8.

Illustration of a representative case of lipid-lactate overlap. (5A) Metabolite maps. In (5B), the lactate doublet peak dominates the pattern which also shows an unequal doublet with higher signal and broadening of the right peak of the doublet. Therefore, the TE_30_lip_lac protocol has been used. Due to T2 relaxation, the lipid component became negligible at TE 135, and only the lactate has been labelled with the TE_135_lac protocol in (5C). In (5D–F), lipids overwhelm the pattern. Since lactate is neither detected on TE 135, nor a ‘hump’ is observable on TE 30, the protocol TE_30_lip_lac is inappropriate.

Line curve fitting in syngo via software. Lactate-lipid compositions are slightly different in (7A) and (7B).
Curve fitting based on chemical peaks. By lactate proportions of lipid and lactate reliably delineated. However, the as erroneous lipid shift assignments should be made.

Diagnostic Radiology
Helmut Rumpel, Ph.D.

References

Conclusion
- Carefully labelled spectra in the lactate–lipid region are a prerequisite to sending them to a PACS system as otherwise they can be misleading for further examinations and treatment planning by clinicians.
- Curve fitting based on chemical shift assignments should be made with caution. The technologist is required to identify what is what, as erroneous lipid-lactate discrimination is inherent to frequency domain curve fitting of overlapping peaks. By following basic steps, the lactate-lipid overlap within the region from 0.9 to 1.3 ppm can be reliably delineated. However, the proportions of lipid and lactate remain ambiguous as various sets of model peaks, i.e. half-width, signal intensity and chemical shift, may lead to the same result of curve fitting.
- Incorporation of prior knowledge such as supportive model spectra automates the curve fitting of a lactate-lipid overlap. The protocol TE_30_lip_lac can be made standard practice.

T1-weighted Phase Sensitive Inversion Recovery for Imaging Multiple Sclerosis Lesions in the Cervical Spinal Cord

Bart Schraa, MSc., Senior MR Application Specialist
Siemens LTD Canada

Introduction
Multiple sclerosis (MS) is an inflammatory disease in which the insulating covers of nerve cells in the brain and spinal cord are damaged. Magnetic resonance imaging (MRI) was first used to visualize multiple sclerosis (MS) in the upper cervical spine in late 1980 [1]. Spinal MS is often associated with concomitant brain lesions; however, as many as 20% of patients with spinal lesions do not have intracranial plaques [2]. This article describes the experiences with a T1-weighted phase sensitive inversion recovery sequence for the detection of MS lesions in the cervical spinal cord using the MAGNETOM Skyra with syngo MR D13A software.

Inversion Recovery Sequences used for imaging Multiple Sclerosis
Several inversion recovery techniques are used for imaging lesions in MS. Among these are Fluid Attenuated Inversion Recovery (FLAIR), Sampling Perfection with Application optimized Contrasts using different flip-angles (SPACE), Double Inversion Recovery (SPACE-DIR), and T1-weighted Phase Sensitive Inversion Recovery (PSIR).

Fluid Attenuated Inversion Recovery
FLAIR is commonly used to assess white matter lesions and in particular MS lesions in the brain. The FLAIR technique is a T2-weighted sequence with a long TR and TE and is used to demonstrate the changes in T2 relaxation times in lesions when compared to normal tissue. As the name indicates, the signal of cerebrospinal fluid (CSF) is attenuated. CSF has a long T1 relaxation time compared to the other tissues in both the brain and cervical spine. Therefore, a rather long inversion time is needed to null the signal of CSF (~2500 ms). Hence, the contrast in T2-weighted FLAIR images allows for easier assessment of MS lesions, especially when the lesions are close to CSF, as compared to normal T2-weighted images. However, while the FLAIR technique works well in the brain, it is hampered by flow and motion artifacts when used in the cervical spine.

Double Inversion Recovery
The Double Inversion Recovery technique has been implemented in the SPACE-DIR sequence in the Siemens syngo MR D13 software. A protocol optimized for brain imaging is also provided: SPACE-DIR is a T2-weighted technique which uses two inversion pulses, combined with a fat saturation pulse, to null both the signal of CSF and normal white matter. Similar to the FLAIR technique, this sequence is used to exploit the changes in T2 relaxation times in lesions when compared to normal tissue. In the brain, SPACE-DIR improves visualization of the cortex and reveals cortical lesions as hyperintense relative to normal surrounding gray matter. It also provides a high contrast between white matter lesions and the surrounding normal white matter. Initial studies have investigated the applicability of SPACE-DIR for lesion imaging in the spinal cord with positive results [3]. Nevertheless, while SPACE-DIR provides a high contrast and isotropic voxels, its rather long acquisition time (~8 min) may prove challenging within a clinical setting.

T1-weighted phase sensitive inversion recovery
A promising potential alternative for imaging MS lesions in the cervical spinal cord [4], is the T1-weighted true or phase sensitive inversion recovery (PSIR) sequence. This technique has been used to detect MS lesions both in white and cortical gray matter in the brain [5, 6]. This sequence exploits the differences in T1 relaxation times of tissues rather than the differences in T2 relaxation times as for both FLAIR and SPACE-DIR.

Since the inversion time used is chosen such that it nulls the signal of normal white matter (~350–400 ms @ 3T), normal white matter is displayed as intermediate gray. All other tissues will have either lower or higher signal intensity than normal white matter depending on their T1 relaxation time relative to normal white matter. This provides a high contrast between MS lesions and surrounding tissue. Moreover, because PSIR uses a short TE, it is less sensitive to flow artifacts. High resolution imaging can also be achieved within reasonable scan times.

Based on these advantages, T1-weighted PSIR is now being explored for the detection of MS lesions in the cervical spinal cord.

Reconstruction methods
The T1-weighted PSIR images can be reconstructed as a magnitude or a phase sensitive (real) image (Fig. 1).

Magnitude reconstruction
The magnitude reconstruction does not consider the sign of the signal. Therefore, the tissue which is nulled by the inversion time will have a signal intensity of zero and all other tissues will have higher signal intensity (ranging from 0 to +4096), regardless of whether they have shorter or longer T1 relaxation time than the nulled tissue (Fig. 2). However, there is a range of inversion times where the contrast between two different
tissues, e.g., lesion and normal tissue, can be decreased or even disappear. This range depends on T1 relaxation times of the two tissues and range between the two inversion times that would null one or the other tissue. In the example shown in figure 5, it ranges from approximately 390 to 430 ms. An example of the magnitude image is shown in figure 4A.

Phase sensitive reconstruction
In the phase sensitive reconstruction, the sign of the signal is taken in account for the reconstruction of the image (Fig. 5). As opposed to the magnitude reconstruction where the signal intensity in the image ranges from 0 to +4096, for the phase sensitive reconstruction it ranges from -4096 to +4096. This results in an image where the tissue which is nulled by the inversion time will be displayed as intermediate gray and all other tissues will have a lower or higher signal intensity depending on their T1 relaxation times relative to the T1 relaxation time of the nulled tissue. Tissues with a shorter T1 relaxation time will have a higher signal (e.g. fat), whereas tissues with a longer T1 relaxation time will have lower signal (e.g. CSF). Unlike the magnitude reconstruction, the contrast between tissues remains largely preserved independent of the chosen inversion time. Since the T1 relaxation time of lesions might vary from patient to patient and even from lesion to lesion, the phase sensitive reconstruction should be used to reconstruct the images. An example of the phase sensitive reconstruction is shown in figure 4B.

Clinical Cases
Case 1
Patient with a MS lesion at the level of C6 (Fig. 6). The lesion is difficult to see on the T2- and PD-weighted images. However, the MS lesion can be clearly seen in the T1-weighted PSIR image.

Case 2
Patient with diffuse MS lesions in the spinal cord from level C3 to C6 (Fig. 7). The lesions are hardly visible on the T2- and PD-weighted images, whereas the T1-weighted PSIR shows the lesions more clearly.

Case 3
Patient with a known MS lesion at the level of C3-C4 (Figs. 8A–C) and C7-T1 (Figs. 8D–F). The lesion at the level of C3-C4 can hardly be seen on the T2-weighted image. Both the PD- and the T1-weighted PSIR show this lesion clearly. While the lesion at the level of C7-T1 is poorly visible on the T2- and PD-weighted images, the T1-weighted PSIR shows it very clearly.

Imaging Parameters
The parameters for the sequences used in the clinical cases are listed in table 1.

Conclusion
The T1-weighted PSIR shows great potential in revealing MS lesions in the cervical spinal cord. While using this technique it is important to use the phase sensitive reconstruction to preserve the contrast between MS lesions and normal appearing tissue. Due of the nature of the reconstruction, and because T1 values of lesions can vary from patient to patient, for reliable depiction of lesions, the phase sensitive reconstruction is recommended. This is as, unlike the magnitude reconstruction, the phase sensitive reconstruction provides a contrast between different tissues that is largely independent of the chosen inversion time.

Pictorial Essay

Benign and Malignant Bone Tumors: Radiological Diagnosis and Imaging Features

Katharina Grünberg, M.D.; Christoph Rehnitz, M.D.; Marc-André Weber, M.D., M.Sc.

Section Musculoskeletal Radiology, Diagnostic and Interventional Radiology, University Hospital Heidelberg, Germany

Topics

The learning objectives of this review article are to identify benign vs. malignant criteria in bone tumor diagnosis and also to differentiate the types of bone tumors and their characterization. Based on the Lodwick classification, an overview of the three main types of bone destruction patterns visible on radiographs will be given with many examples. Typical examples of benign and malignant bone tumors will be demonstrated, and the various imaging modalities will be compared, and their utility will be discussed. The image gallery comprises pearls and pitfalls. Presentation of standardized magnetic resonance imaging (MRI) protocols will be given. Of course, this pictorial essay does not have the focus of comprehensively presenting all bone tumor entities.

Introduction

Primary bone tumors are categorized according to their tissue of origin into cartilage, osteogenic, fibrogenic, fibrohistiocytic, haematopoietic, vascular, lipogenic tumors and several other tumors, like Ewing sarcoma and giant cell tumor [1]. Thy are also classified as either benign, malignant or semi-malignant, as well as tumor-like lesions [2]. They are rare, but found on radiographs during an investigation like lesions [2]. They are rare, but found on radiographs during an investigation of a painful skeletal region or incidentally, e.g. when performing a joint or whole-body MRI. You will need four diagnostic columns to make a diagnosis of a bone tumor.

Four diagnostic columns (Fig. 1)

1. Malignant vs. benign?
   - X-rays: Aggressiveness: Analysis of growth rate (Lodwick classification), periosteal reaction?
   - Further imaging modality → CT, MRI?
   - Make a specific diagnosis.
2. Analysis of tumor matrix: X-rays, CT:
   - Osteolytic, osteoblastic, mixed
3. Location within the tumor-bearing bone: Epi-, meta-, diaphysis
4. Patient’s age, (affected bone)

Tumor's aggressiveness

The radiograph is the first method to distinguish benign from malignant lesions; at first by analysing the aggressiveness (analysis of growth rate) of a lesion according to the classification of Lodwick [3]. In radiography there is a correlation between bone tumor's growth rate and dignity. If you identify an aggressive growth pattern and/or malignant periosteal reaction another imaging modality like computed tomography (CT) or magnetic resonance imaging (MRI) is needed. MRI is important for defining the extension of tumor before biopsy.

Tumor matrix

In a second step, it is essential to analyze the mineralisation of tumor matrix in radiographs or CT. The matrix may be osteolytic, osteoblastic, or mixed, i.e. osteolytic with matrix mineralisation.

Lodwick classification (Fig. 2)

Based on the Lodwick classification, an overview of the three main types of bone destruction patterns visible on radiographs are given with a representative example:

Type 1: geographic (with a well-defined border with sclerotic rim, b: well-defined and sharp border but without sclerotic rim, c: ill-defined and blurred border).
Type 2: geographic with moth-eaten or permeated pattern (patchy lysis),
Type 3: small, patchy, ill-defined areas of lytic bone destruction with moth-eaten or permeated pattern (patchy lucrencies) [3, 5].

Lodwick classification: An overview of the three main types of bone destruction patterns with representative image examples.
Criteria of malignancy (Fig. 3)

Periosteal reactions are also indicators of lesion aggressiveness and can be differentiated according to a benign (thick, dense, wavy) type or an aggressive (tumored, amorphous, sunburst) type. Figures 3A–D show an example of an 80-year-old man with a cloudy inhomogeneous tumor of the distal humerus with perpendicular periosteal reaction of a malignant (sunburst) type. Aggressive (lamellated, amorphous, (thick, dense, wavy) type or an example of an 80-year-old man with a cloudy inhomogeneous tumor of the distal humerus with perpendicular periosteal reaction of a malignant (sunburst) type.

Types of bone tumors

According to their type of matrix (osteolytic, osteoblastic, or osteolytic with matrix mineralization) and to their tissue of origin, bone tumors are categorized into different types: osteoid, chondroid, fibrous, lipoid/fatty, other, cystic (solitary bone cyst), vascular (hemangiomia), special cell type: Giant cell (osteoclastoma), small cell (Ewing’s sarcoma), histiocytes (eosinophilic granuloma), plasma cells (multiple myeloma), notochordal cells (chordoma) and metastases.

Osteoid type

Osteoid osteoma and Osteoblastoma (Fig. 4)

This entity is frequent: around 13.5% of all benign bone tumors are osteoid osteomas. The patients are usually younger than 30 years and suffer “night pain relieved by aspirin” and other platelet aggregation inhibitors. The main location is in more than 50% within diaphysis of long bones and in 10% within the vertebral column with painful scoliosis. Osteoid osteomas show in CT and X-ray a perifocal sclerotic lesion with a central lucency (nidus) that is cortically based in 80% Medullary, subperiosteal and articular locations also occur. Calcification of the nidus is possible. The nidus is extremely vascular in contrast-enhanced MRI and it is important to identify the nidus as the tumor itself; surrounding sclerosis and bone marrow edema pattern is just reactive. It should be noted that lesions may have less or no sclerosis if the nidus is located in the marrow or in an adjacent to a joint (Fig. 5). Osteid osteoma resembles osteomyelitis. For example if a Brodie’s abscess is in an eccentric position, e.g. cortically located, it is difficult to differ Brodie’s abscesses from osteoid osteoma. The differentiation can then only be done by biopsy or radionuclide bone scan.

Osteoid osteoma shows – in contrast to osteomyelitis – the “double density sign” (i.e. a high intense central activity surrounded by an area of medium activity). A lesion larger than 1.5 cm is called osteoblastoma [7, 11]. Radiofrequency ablation (RFA) is a successful treatment [8, 9, 10].

Keys to diagnosis: Sclerotic lesion with a small lucency in X-ray. The nidus shows a high signal on T2-weighted MR images and has a strong contrast-enhancement.

Keys to diagnosis: Sclerotic lesion with a small lucency in X-ray. The nidus shows a high signal on T2-weighted MR images and has a strong contrast-enhancement.
Osteosarcoma

The patients are usually younger than 20 years. A 2nd peak exists in the 5th decade and these cases are mostly secondary in Paget’s disease and after irradiation. Osteosarcoma has a predilection for sites of rapid bone growth, usually the metaphyseal region. Typical symptoms are pain and local swelling. This entity shows typically destructive periosteal reactions as mentioned above (Fig. 6). Their X-ray morphology is very variable: Osteosarcomas may be osteogenic (i.e. the tumor induces new bone formation), lytic or mixed, which is the common manifestation form (Fig. 7) [12]. If such a lesion is lytic, consider also telangiectatic osteosarcoma! From origin, sclerosis grade and soft tissue component, osteosarcomas are separated into a central, parosteal (originates from the periosteum) and a periosteal variant, which is very rare (1% of osteosarcomas). In periosteal osteosarcomas the process starts either in the periosteum or adjacent soft tissue. Typical—in contrast to parosteal osteosarcoma—the periosteal osteogenic sarcoma does not have large amounts of calcification in the soft tissue (Fig. 8) [11]. Osteosarcomas may produce osteoblastic lung metastases (Fig. 9).

Keys to diagnosis are to detect criteria of malignancy in X-ray and further imaging modalities: CT is the best for identifying periosteal reaction versus tumor matrix because you can already see faint mineralization in CT. In MRI the signal depends on the degree of matrix mineralization. But MRI is important for assessing the tumor extent and for staging purposes, i.e. to identify skip lesions, to assess the soft tissue, nerve and vessel involvement, and a potential joint infiltration.

17-year-old male patient with articular osteoid osteoma (OO) of the left knee joint. (5A–C) Axial, sagittal and coronal CT with the articular position of the OO show no sclerosis of the nidus-margin (orange circle). In CT you see well that the nidus shows some central ossifications. The axial T2w MRI with fat saturation (5D) demonstrates the joint effusion and synovitis (yellow arrow). You can also see well that because of the central nidus calcifications the OO has only isointense to less hyperintense signal in T2w (orange circle) instead of the typical strong hyperintense signal (SE) Sagittal PDw MRI also shows the calcification. (5F) Axial contrast-enhanced T1w MRI with fat saturation demonstrates the enhancing nidus (orange circle).

21-year-old man with a central high-grade osteosarcoma in the distal left femur. Conventional osteosarcomas are the central osteosarcoma placed in the center of the metaphysis. Figure 6A shows the antero-posterior and (6B) the lateral radiograph. In this case you can see in addition to periosteal reactions (orange arrow in 6A) the channel-shaped lucency in the radiograph correlating with the biopsy channel (yellow arrow in 6D) within a disorganization of the bone pattern and osteoid formation (orange circle in 6B). You also see the biopsy channel in the coronal T1 weighted MRI (orange arrow in 6C). Figure 6D demonstrates the heterogeneity of the tumor mass (axial T2w MRI with fat saturation). Performing MRI is important for preoperative local staging, e.g. in this case the vessel infiltration (orange arrows in 6E) is visible in the axial post-contrast T1 weighted MRI.

These images demonstrate well the difference between osteogenic versus lytic osteosarcoma. Figures 7A (antero-posterior radiograph of the lower leg) and 7B (sagittal contrast-enhanced T1w MRI with fat saturation of the lower leg) show an osteogenic parosteal osteosarcoma of the left tibia, a bone forming tumor with fluffy, amorphous, cloudlike mineralization (orange arrow in 7A) beside sunburst periosteal reaction as a criterion of malignancy (5 in 7A). This tumor has a big soft tissue component (yellow arrow in 7B) with large amounts of calcification (yellow arrow in 7A). Figures 7C (antero-posterior radiograph of the pelvis) and 7D (sagittal contrast-enhanced T1w MRI with fat saturation) show a more lytic osteosarcoma of a 61-year-old female patient in the right os ilium with no mineralization (orange arrow).
63-year-old female with osteoblastic lung metastases one year after resection of an osteosarcoma of the left thigh. Axial CT images (9A–C) show several osteoblastic lung metastases of a bone producing primary tumor: an osteosarcoma. Therefore the lung metastases may be also sclerotic.

Chondroid type

Enchondroma

Enchondroma is a benign lytic lesion typically placed in the hand and chiefly centrally located, often with endosteal scalloping. It must have calcification except in the phalanges (Fig. 10). A typical size of enchondroma is around 1–2 cm; low grade chondrosarcoma is larger than 4–5 cm. The enchondroma shows no periosteal reaction. An important differential diagnosis is the bone infarction (Fig. 12).

Keys to diagnosis are: In T1-weighted MR imaging the lesion has a low signal. The T2-weighted signal depends on the degree of calcification. After contrast enhancement the tumor shows in T1-weighting MR imaging a lobulated appearance with septa (Figs. 10 and 11).

Suspicious of malignancy in chondroid tumors are pain, a size larger than 5 cm, the presence of a soft tissue mass and a growing surrounding edema on T2-weighted images.

Multiple enchondromas occur on occasion, a condition called Ollier’s disease. This is not hereditary and with no increased rate of malignant degeneration.

By contrast, Maffucci’s syndrome is a condition with multiple enchondromas associated with soft tissue hemangiomas. Maffucci’s syndrome is likewise not hereditary, but is characterized by an increased incidence of malignant degeneration of the enchondromas [11].

67-year-old female patient with a periosteal osteosarcoma (G3) of the right lower leg. Figure 8A, anteroposterior radiograph of the right knee shows saucerization of the tibial metaphysis (orange circle) and also a bone prominence (yellow arrow). BB (coronal T1w MRI of the lower right leg) and BC (sagittal T1w MRI of the lower right leg) show the big inhomogeneous tumor with a large soft tissue component. Keep in mind that the periosteal osteogenic sarcoma does not have large amounts of calcification in soft tissue as shown in 8A–C (orange circle). Figures 8D (axial T2w MRI with fat saturation) and 8E (axial contrast-enhanced T1w MRI with fat saturation) clearly demonstrate that the tumor inexplicably will not invade the medullary space of the tibia (orange circle) and that the fibula is not involved (yellow arrow).

29-year-old female with an enchondroma of the phalanx D1. (10A) Lateral radiograph of the right D1 shows the lytic lesion in the proximal metacarpus of D1 which is hardly to identify and without sclerotic rim, according to a Lodwick IB lesion (orange circle) and without calcifications. (10B–F) show the typical signal characteristics of an enchondroma in MRI (orange circles): low signal in T1-weighted imaging (10B, coronal), high signal in T2-weighted imaging because of absent calcification as shown in 10A (10E, axial T2w MRI with fat saturation). Coronal contrast-enhanced T1w MRI (10D), coronal T1w MRI subtraction (10D), and axial contrast-enhanced T1w MRI with fat saturation (10F), show that the tumor has a lobulated appearance with septa.
44-year-old female with an enchondroma within the humeral head. (11A) Antero-posterior radiograph of the shoulder, (11B) coronal CT of the shoulder, (11C) coronal 12w MRI with fat saturation, (11D) coronal T1w MRI, (11E) coronal contrast-enhanced T1w MRI. 11A and B show a lesion bigger than 2 cm with a sharp border (Lodwick IB) in the humerus head with the following different forms of calcification of the chondral tissue: Punctate, comma-shaped, arc like, ring like mineralization (orange circle). In T1w the tumor shows low signal (11D), in T2w with fat saturation high signal with some low signals according to the calcifications, thus containing no fat and post-contrast a homogenous contrast-enhancement with a rough lobulated pattern (11E) (yellow arrows).

40-year-old female with a bone infarction in the right tibia and femur. (12A) Antero-posterior, (12B) lateral radiograph of the knee, (12C) coronal contrast-enhanced T1w MRI, (12D) coronal T2w subtraction MRI, (12E) axial contrast-enhanced T1w MRI with fat saturation, (12F) axial T2w MRI with fat saturation, (12G) coronal STIR MRI. An infarct usually has a well-defined, densely sclerotic, serpiginous border as well shown in 12A and B (orange circles) and in MRI in 12C-G (yellow arrows), whereas an enchondroma does not. Fat in the lesion as seen in 12C, E and G (yellow stars) is a hint of bone infarction and speaks against an enchondroma.
Chondroid type

Osteochondroma (Fig. 13)
A synonym for osteochondroma is cartilaginous exostosis. It is a common benign tumor of the extremities (10%–15% of all bone tumors) and is located in 50% of cases in the lower extremities, in 10–20% in the humerus, but rarely in the spine. For the diagnosis it is important to identify the continuation of bone marrow and trabecular bone structures into the exostosis as well as the cartilage cap. The malignant degeneration occurs mainly in tumors near the trunk. Key to diagnosis is a mushroom-like tumor. The thickness of the cartilage cap is 8 mm or more (threshold in our institution, see also explanation in the next chapter) (Fig. 13) [13]. Contrast media is not needed to determine the thickness of the cartilage cap, because it is clearly visible on T2-weighted images.

Osteochondroma vs. chondrosarcoma
A malignant transformation is more likely if the cartilage cap thickness is 8 mm or more, which is the threshold of our clinic. Further publicized threshold values are 1.5 cm according to Murphey et al. [14] and 2.0 cm according to Bernard et al. [15]. Proximity to trunk (location in the pelvis with highest malignant transformation rate!) and hereditary multiple exostoses (autosomal dominant inheritance) (Fig. 14) are correlated with a higher risk of malignant transformation (3–5% of tumors develop into chondrosarcomas). A further criterion is a cartilage cap growth, especially beyond age 20. Note: It is extremely difficult for either a radiologist or a pathologist to differentiate a low-grade chondrosarcoma from enchondroma (Fig. 15).
Chondrosarcoma (Figs. 15–17)

Patients are mostly older than 40 years and experience pain. Tumors are near the trunk and have a chondroid matrix. Chondrosarcomas are characterized by slow growth. Primary chondrosarcomas are lytic, permeative and destructive lesions with calcification in 50%. Secondary chondrosarcomas have a cartilage cap’s thickness larger than 8 mm as a sign of malignant transformation of an osteochondroma (see also the comments to threshold value in the last chapter) [13-15].

Keys to diagnosis are lytic, destructive lesion with flocculent, snowflake or popcorn calcification in patients older than 40 years. MRI: soft tissue mass or edema. The following criteria are in favor of a chondrosarcoma as opposed to an enchondroma: Pain, tracer uptake in bone scan, growth, cortical bone penetration.

31-year-old male patient with grade 1 chondrosarcoma of the right os ilium. (15A) The antero-posterior radiograph of the right hip joint shows a geographic well-defined lytic lesion in the right acetabulum with a sharp border but without sclerotic rim according to a Lodwick IB lesion (orange arrow), in the center there is some flocculent calcification. (15B) Coronal CT and (15E) axial CT of the right hip show the lytic lesion with sharp border, thinned cortex and central punctuate calcification without cortical destruction. (15D, E) Contrast-enhanced T1w MRI with fat saturation (coronal in 15D and axial in 15E) show a central contrast enhancement. Figure 15F shows a coronal STIR MRI with a high signal in the border area of the tumor.

33-year-old female with grade 2 chondrosarcoma of the left olecranon. 16A shows an antero-posterior radiograph of the left olecranon with a Lodwick type IC lesion: geographic but blurred border (orange circle). Figure 16B shows the lateral radiograph of the left olecranon and reveals a cortical destruction (orange arrow). (16C) Coronal STIR MR image clearly shows the intramedullary borders of the tumor (orange arrows). (16D) Axial T2w MR with fat saturation shows the chondroid matrix of the tumor (orange circle). (16F) Sagittal T2w MR shows the hypointense calcification (orange arrow) in the center of the chondroid tumor. (16G) Sagittal contrast-enhanced T1w MRI with fat saturation shows the infiltration of the surrounding soft tissue (orange arrow).

58-year-old male patient with grade 3 chondrosarcoma of the right humerus. (17A) The antero-posterior radiograph of the right humerus shows in addition to a patchy lysis pattern (Lodwick III) the cortex destruction (orange circle). (17B) Coronal STIR MR clearly shows the extension of this large amorphous lesion (size of 10 cm, long yellow arrow) and the soft tissue infiltration (small yellow arrow). The tumor has a predominant chondroid matrix with low signal in T2w (17D) and also shows an inhomogeneity high signal in T2w (17D) and T1w (17E) as a further hint of a high-grade chondrosarcoma. (17G) Also shows the cortex destruction and soft tissue infiltration (orange circle). (17B) Coronal contrast-enhanced MRI shows necrotic tumor areas within the tumor (yellow arrows). Also areas without chondroid matrix are a hint of a high-grade chondrosarcoma.
Chondroblastoma (Fig. 18)
Patients are usually younger than 20 years (i.e. skeletally immature patients). The lesion must be located epiphysially and is rare in metaphysis. This entity also occurs in carpal and tarsal bones and rarely in the patella (which with regard to the differential diagnosis of lytic lesions behaves like an epiphysis) [11]. Usually it appears in long bones and shows in 40–60% calcification. Differential diagnoses are the sequestrum (osteomyelitis) and the eosinophilic granuloma.

Key to diagnosis: Chondroblastomas are lytic epiphyseal lesions with sclerotic rim. In MRI it shows a chondroid component with high signal in T2-weighted imaging and calcification with low signal in T2-weighted imaging [4].

Fibrous type
Non-ossifying fibroma – NOF (Figs. 19 and 20)
Patients are usually younger than 20 years and have no pain or periosteal reaction. This lesion is located in the metaphysis of long bone in eccentric position and emanates from the cortex, so that the cortex will be replaced with benign fibrous tissue. Non-ossifying fibromas ‘heal’ with sclerosis and disappear in the following years. Lesions smaller than 3 cm in length are called fibrous cortical defect and lesions larger than 3 cm in length are called non-ossifying fibroma.

Key to diagnosis: A lytic lesion with expansive growth and scalloped, well-defined sclerotic border. The MRI appearance of an NOF is somewhat variable. Although they are essentially always low signal on T1-weighted MR imaging, they can have high or low signal on T2-weighted imaging. NOF has partly homogeneous or partly non-homogeneous contrast-media enhancement. During the ‘healing period’ the non-ossifying fibroma can be hot on radionuclide bone scans indicating the osteoblastic activity.
Fibrous dysplasia (Figs. 21–23)
Patients have usually no pain or periosteal reaction. Fibrous dysplasia can be either monostotic (most commonly) or polyostotic (McCune-Albright syndrome) and has a predilection for the pelvis, the proximal femur, the ribs and skull. In its classic description, fibrous dysplasia has a ‘ground-glass appearance’ or ‘smoky appearing’ in X-ray and/or CT (Fig. 21), but the ground glass appearance is not always present. Lesions may be mixed lytic and sclerotic [11] and bone may be deformed.

Keys to diagnosis are: No periosteal reaction. Fibrous dysplasia shows lytic lesions, as the matrix calcifies it has a hazy, smoky and ground-glass look to the point of sclerotic lesion. The signal alterations of fibrous dysplasia in MRI follow the uniform pattern of all tumors (low signal in T1-weighted and intermediate to high signal in T2-weighted images). The fibrous tissue enhances contrast media. If the lesion is located in the tibia, consider also adamantinoma, which has malignant potential, i.e. a mixed lytic and sclerotic lesion in anterior cortex of tibia that resembles the fibrous dysplasia.
Image gallery of fibrous dysplasia: "Fibrous dysplasia can look like almost anything" [11], as is clearly visible when you compare the following three cases.

(22A) Antero-posterior radiograph of the pelvis of a 34-year-old male patient clearly shows that the ipsilateral proximal femur is always affected when the pelvis is involved with fibrous dysplasia (orange circles). The lesion in the pelvis is more lytic than the lesion in the femur which is more sclerotic. (22B) Antero-posterior radiograph of the right knee of a 33-year-old female patient shows a circumscripted lytic lesion of the distal femur with smoky parts (orange arrow). (22C) Lateral radiograph of the left lower leg of a 23-year-old male patient with a fibrous dysplasia of the tibia shows a lytic lesion in the tibia with cortical destruction (orange arrow). MRI and biopsy were needed to confirm the diagnosis. Figures 22D–F show the corresponding MRI images to this case: (22D) Coronal T1-weighted MR image shows the classically low signal of lesion. (22E) Sagittal T2-weighted MR image and (22F) axial T2-weighted MR image with fat saturation show that the lesion is inhomogeneous.

34-year-old male patient with a polyostotic fibrous dysplasia in pelvis and proximal femur (Albright-syndrome).

(23A) Antero-posterior radiograph of the pelvis, (23B) antero-posterior radiograph of the left femur and (23C) lateral radiograph of the left femur show lots of lesions with smoky appearance in the right ischium and the left femur (orange arrows). (23D) Coronal T1-weighted MR image of the left femur shows a low signal of the lesions (orange arrow). (23E) Coronal STIR MR image of the left femur shows an intermediate to high signal of the lesions (orange arrow) and (23F) axial contrast-enhanced T1-weighted MR image shows an inhomogeneous contrast-enhancement of the fibrous tissue (orange arrow).
Lipoid/fatty type
Calcaneus lipoma (Fig. 24)
A common location is the calcaneus. It is a rare entity and a so-called ‘leave-me-alone lesion’. Key to diagnosis: Fat signal in all MRI sequences.

Other types
Solitary bone cyst (Figs. 25, 26)
Patients are usually younger than 20 years. Common location: calcaneus, proximal humerus and femur with central location of the lesion. Patients have no pain or periosteal reaction unless they suffer a fracture through this lesion. The fracture often produces fragments that sink to the bottom of the lesion, well known as the ‘fallen fragment sign’ visible on radiographs. Key to diagnosis: Lytic centrally located lesion, well-defined with sclerotic rim (Lodwick type A). The MRI shows non-enhancing pure fluid (in contrary to aneurysmal bone cyst).

If the lesion is located in the calcaneus think about the differential diagnosis of an intra-osseous lipoma. A differentiation by X-ray is then only possible if the lipoma has a central calcification. But this differentiation is not relevant, because both lesions are ‘leave-me-alone lesions’ [11].

Image gallery of solitary bone cyst with the ‘fallen fragment sign’. (26A) Antero-posterior radiograph of the right shoulder of a 9-year-old female patient with the ‘fallen fragment sign’ in a solitary bone cyst of the humerus (orange arrow).

Figures 26B–E show the case of an 11-year-old patient with a solitary bone cyst also in the right humerus. (26A) Antero-posterior radiograph of the right shoulder demonstrates well the pathognomonic ‘fallen fragment sign’ of the cystic lesion.

(26C) Shows a coronal T1w MRI with low signal of the lesion and (26D) shows an axial T2w MRI with a small fluid level between the cystic fluid and the blood after the occurred fracture (orange arrow). Usually solitary bone cysts show no fluid fluid levels as it is typical for the aneurysmal bone cyst. (26E) Coronal contrast-enhanced T1w MRI with fat saturation shows non-enhancing pure fluid.

Aneurysmal bone cyst (ABC) (Fig. 27) The patients are usually younger than 20 years. At the vertebral column, this entity often occurs at the posterior elements of the vertebral bodies. It shows an aneurysmal, expansive growth with thinned cortex or neo-cortex (ballooned cortices) called ‘blow-out’ phenomenon in CT.

Key to diagnosis: The aneurysmal bone cyst is a lytic geographic lesion, eccentrically located with extensive thinning of the cortex. Sedimentation effects of blood-filled cysts with fluid-fluid levels and contrast enhancement of the cystic wall and the septa are typical signs in MRI. If there are solid contrast-enhancing parts consider secondary ABC with other tumors (e.g. giant cell tumor, osteosarcoma, chondrosarcoma, chondroblastoma).

17-year-old male patient with an aneurysmal bone cyst of the right glenoid. (27A) Lateral radiograph of the right shoulder shows a geographic lesion in the glenoid without sclerotic rim, Lodwick IB (orange arrows). (27B) Coronal CT of the right shoulder shows a lytic, expansible lesion with a thinned cortex (yellow arrow). (27C) Axial T2w non-fat-saturated MRI shows the cystic parts with fluid-fluid level (yellow arrow). (27D) Axial contrast-enhanced T1w MRI shows the enhancement of the septa (orange circle).
Giant cell tumor (Fig. 28)
A precondition is that the epiphysis is closed. This tumour often abuts the articular surface and most often has an eccentric localization. Often a well-defined lesion with a non-sclerotic margin (Lodwick IB). Local aggressive growth and lung metastasis in 5–10% occur.

Key to diagnosis: Osteolytic eccentric, epiphyseal lesion without matrix calcification and extensive thinning of the cortex. The tumor shows low signal in T1-weighting, inhomogeneous or low signal in T2-weighting and contrast enhancement. If the tumor contains necrosis and hemosiderin, this results in an inhomogeneous contrast enhancement pattern.

Ewing’s sarcoma (Figs. 29, 30)
The classic Ewing’s sarcoma is a permeative lesion in the diaphysis of long bone in a child, with osteodestruction in CT and a very high signal in T2-weighted imaging indicating infiltration of bone marrow. The location of Ewing’s sarcoma tends to follow the distribution of red marrow.

In histology small round blue cells are visible. A large soft tissue mass is possible. Important differential diagnoses are osteomyelitis and eosinophilic granuloma, which have a benign periosteal reaction and sometimes a sequestrum.

Key to diagnosis: A permeative lesion or lesion with sclerotic and patchy appearance and periosteal reaction which can be onion-skinned (multilaminated), sunburst or amorphous. Low signal in T1-weighted MR images, high signal in T2-weighted MR imaging with strong contrast enhancement. More than 50% are osteolytic lesions. Edema and large soft tissue mass often occur.
Multiple myeloma (Fig. 31)
In multiple myeloma, a proliferation of monoclonal plasma cells within the bone marrow occurs. The vertebral column is mostly affected and 70% of patients are older than 60 years. Multiple lytic lesions in an adult older than 40 years almost always suggest metastases or multiple myeloma. Bone sarcomas are rare, and the most common cause of a solitary destructive lesion in an adult is a metastasis. Low-dose CT is important for proving osteolytic lesions and MRI [22] for proving bone marrow affection: Decrease of T1-weighted signal in bone marrow infiltration compared to the disks, and a signal increase in the STIR images compared to muscle tissue. Whole-body MRI is suitable for demonstration of the tumor burden. It is important to think of patient’s age when interpreting T1-weighted MR imaging, because young patients still have a cell-rich red bone marrow and therefore also a low T1 signal. We differentiate three patterns of bone marrow infiltration: diffuse, multifocal, or salt-and-pepper pattern. Salt-and-pepper pattern indicates a low grade disease stadium. A single lesion is called plasmacytoma [22, 23].

Metastases (Fig. 32)
45% of all metastases are located in the vertebral column. The most frequent primary tumors are lung, breast, prostate, renal cell, gastrointestinal and thyroid carcinomas. Bone marrow infiltration happens before osseous destruction. It is important to pay attention to fractures, spinal canal invasion and myelon compression. Key to diagnosis: For the diagnosis of bone metastases a low signal in T1-weighted MR images is more sensitive than osteolysis in CT [24]. Osteolytic metastases have a high signal in T2-weighted images, whereas osteoblastic metastases have a low to isointense signal in T2-weighted images. Take into account these factors in older patients and consider several osteoblastic and/or osteolytic lesions.
Summary
Role of X-ray
In addition to patient history and clinical findings, a radiograph in two orthogonal planes is still of great importance for determining the Lodwick classification and the tumor matrix, whereas the bone matrix is only poorly visualized in X-ray. You cannot differentiate between lesions containing fluid and solid lesions without mineralized matrix. In general, conventional X-ray radiography is the starting point and CT and MR images should only be interpreted with concurrent radiographic correlation.

Role of CT
CT is superior to MR for the assessment of mineralized structures especially cortical integrity, matrix mineralization, and periosteal reactions [21]. Small lucency of the cortex, localized involvement of the soft tissues, and thin peripheral periosteal reaction can be best seen with CT [16]. CT is the examination of choice in the diagnosis of the nidus of osteoid osteoma in dense bone [17]. CT is valuable in the diagnosis of tumors of the axial skeleton such as spinal metastasis as well as in systemic staging.

Role of MRI [18-21]
Without any radiation MRI can be helpful while evaluating lesions that represent a differential diagnosis dilemma between benign and malignant lesions before a biopsy. For example in aneurysmal bone cysts MRI can display fluid levels in blood filled cavities better. Another example, MRI before biopsy for staging all suspected sarcomas of bone could help identifying extraneous sarcoma better. MRI plays an important role in planning limb salvage surgeries because of its superior role for soft tissue evaluation including the presence or absence of neurovascular invasion [21]. MRI helps by identifying soft tissue and measures the thickness of callus bridge. The cap is thin in benign lesions and thicker in chondrosarcomas [14, 15]. This aids evaluation of the entire compartment of long bones in acceptable time. Important here is a logical approach and an algorithm (for example, see Fig. 33). This in turn helps to improve the quality of life by reducing morbidities and disease survival. MRI is most useful in evaluation of spine metastasis differentiating osteoporotic and metastatic compression fractures. In Multiple Myeloma cases whole-body MRI scans are suitable for demonstration of the tumor burden. Though not yet in clinical routine, newer techniques such as diffusion weighted imaging and DCE-MRI may support assessment of tumor response. More studies are being conducted.

Combined 18F-FDG PET and MRI Evaluation of a case of Hypertrophic Cardiomyopathy Using Simultaneous MR-PET

Ihn-ho Cho, M.D.; Eun-jung Kong, M.D.
Department of Nuclear Medicine, Yeungnam University Hospital, Daegu, South Korea

Introduction
Hypertrophic cardiomyopathy (HCM) is a common condition causing left ventricular outflow obstruction, as well as cardiac arrhythmias. Cardiac MRI is a key modality for evaluation of HCM. Apart from estimating left ventricular (LV) wall thickness, LV function and aortic flow, MRI is capable of studying ventricular outflow obstruction, as is a common condition causing left ventricular dysfunction and aortic flow. MRI is capable of evaluating myocardial blood flow with pharmacological stress in hypertrophic myocardium in HCM, presumably related to microvascular disease [2]. 18F-FDG PET has been sporadically studied in HCM, mostly for evaluation of the metabolic status of the hypertrophic myocardial segment, especially after interventions such as transcatheter ablation of septal hypertrophy (TASH) [3] or to demonstrate partial myocardial fibrosis [4]. This clinical example illustrates the value of integrated simultaneous 18F-FDG PET and MRI acquisition performed on the Biograph mMR system.

Patient History
A 25-year-old man presented to the cardiology department with incidental ECG abnormality after fractures to his left 2nd and 4th fingers. Although he had not consulted a doctor, he had been suffering from mild dyspnea with chest discomfort at rest and exacerbation at exercise since May 2012. Echocardiography revealed non-obstructive hypertrophic cardiomyopathy (Maron III) with trivial MR. The patient was referred for a simultaneous MR-PET study for 18F-FDG PET and cardiac MRI with Gadolinium (Gd) contrast for evaluation of the morphological and metabolic status of the hypertrophic myocardium. The patient was injected with 10 mCi 18F-FDG following glucose loading. Simultaneous MR-PET study performed on a Biograph mMR was started one hour following tracer injection. Following standard Dixon sequence acquisition for attenuation correction, the comprehensive cardiac MRI sequences were acquired including MR perfusion after Gd contrast infusion, as well as post contrast late Gd enhancement studies. Static 18F-FDG PET was acquired simultaneously during the MRI acquisition.

Discussion
The late Gd enhancement within the hypertrophic septum along with the non-uniform glucose metabolism demonstrated by the patchy 18F-FDG uptake within the hypertrophic septum exactly corresponding to the area of Gd enhancement reflect myocardial fibrosis within the asymmetric septal hypertrophy. Myocardial fibrosis and the presence of late Gd enhancement on MRI has been shown to be associated with increased risk of cardiac arrhythmias [1] as evident from the symptoms of this patient.

Simultaneous MR-PET acquisition provides combined acquisition of both modalities, thereby ensuring accurate fusion between morphological and functional images due to simultaneous PET acquisition for every MR sequence. The exact coregistration of the patchy 18F-FDG uptake in the area of Gd enhancement within the hypertrophic upper septum reflects the advantage of simultaneous acquisition.

New Generation Cardiac Parametric Mapping: the Clinical Role of T1 and T2 Mapping

Viviana Maestrini; Amna Abdel-Gadir; Anna S. Herrey; James C. Moon

The Heart Hospital Imaging Centre, University College London Hospitals, London, UK

Introduction

Cardiovascular magnetic resonance (CMR) is an essential tool in cardiology and excellent for cardiac function and perfusion. However, a key, unique advantage is its ability to directly scrutinize the fundamental material properties of myocardium—"myocardial tissue characterization". Between 2001 and 2011, the key methods for tissue characterization have been sequences 'weighted' to the fundamental magnetic property—T1—quantify—the LGE technique in scar (LGE) and T2-weighted imaging for diffusion fibrosis (focal, as in infarction, or diffuse) [7-8], edema [9-10] and amyloid [11], are examples. T1 is lower in lipid (Anderson-Fabry disease, AFD) [12], and iron [13] accumulation. These changes are large in some rare diseases. Global myocardial changes are robustly detectable without contrast, even in early disease. In iron, AFD and amyloid, changes appear before any other abnormality—there may be no left ventricular hypertrophy, a normal electrocardiogram, and normal conventional CMR, for example—generally new information. In established disease, low T1 values in AFD appear to absolutely distinguish it from other causes of left ventricular hypertrophy [12] whilst in established amyloid T1 elevation tracks known markers of cardiac severity [11].

A note of caution, however. Native T1, although stable between healthy volunteers to 1 part in 30, is dependent on platform (magnet manufacturer, sequence and sequence variant, field strength) [14]. Normal reference ranges for your setup are needed.

T1 mapping

Initial T1 measurement methods were multi-breath-hold. These were time consuming and clunky, but were able to measure well diffuse myocardial fibrosis, a fundamental myocardial property with high potential clinical significance [1]. Healthy volunteers and those with disease had different extents of diffuse fibrosis [2], and these were shown to be clinically significant in a number of diseases. T1 mapping methods based on the MOLLI* approach with modifications for shorter breath-holds, better heart rate independence and better image registration for clearer maps, however, transformed the field—albeit still with a variety of potential sequences in use [3-5]. There are two key ways of using T1 mapping: Without (or before) contrast—Native T1 mapping; and with contrast, typically by subtracting the pre and post maps with hematocrit correction to generate the ECV [6].

Native T1

Native T1 mapping (pre-contrast T1) can demonstrate intrinsic myocardial contrast (Fig 1). T1, measured in milliseconds, is higher where the extracellular compartment is increased. Fibrosis (focal, as in infarction, or diffuse) [7-8], edema [9-10] and amyloid [11], are examples. T1 is lower in lipid (Anderson-Fabry disease, AFD) [12], and iron [13] accumulation. These changes are large in some rare diseases. Global myocardial changes are robustly detectable without contrast, even in early disease. In iron, AFD and amyloid, changes appear before any other abnormality—there may be no left ventricular hypertrophy, a normal electrocardiogram, and normal conventional CMR, for example—generally new information. In established disease, low T1 values in AFD appear to absolutely distinguish it from other causes of left ventricular hypertrophy [12] whilst in established amyloid T1 elevation tracks known markers of cardiac severity [11].

The signal acquired is also a composite signal—generated by both interstitium and myocytes. The use of an extracellular contrast agent adds another dimension to T1 mapping and the ability to characterize the extracellular compartment specifically.

Extracellular volume (ECV)

Initially, post-contrast T1 was measured, but this is confounded by renal clearance, gadolinium dose, body composition, acquisition time post-bolus, and hematocrit. Better is measuring the ECV. The ratio of change of T1 between blood and myocardium after contrast, at sufficient equilibrium (e.g. after 15 minutes post-bolus—no infusion generally needed) [15, 16], represents the contrast agent partition coefficient [17], and if corrected for the hematocrit, the myocardial extracellular space — ECV [1]. The ECV is specific for extracellular expansion, and well validated. Clinically this occurs in fibrosis, amyloid and edema. To distinguish, the degree of ECV change and the clinical context is important. A multiparametric approach (e.g. T2 mapping or T2-weighted imaging in addition) may therefore be useful. Amyloid can have far higher ECVs than any other disease [18] whereas ageing has small changes—near the detection limits, but of high potential clinical importance [19, 20]. For low ECV expansion diseases, biases from blood pool partial volume errors need to be meticulous. In 793 consecutive patients (all-comers but excluding amyloid and HCM, measuring outside LGE areas) followed over 1 year, global ECV predicted short-term mortality (Fig. 2).
Progress is rapid, challenges remain. Delivery across sites and standardization is now beginning with new draft guidelines for T1 mapping in preparation. Watch this space.

Introduction

Left ventricular (LV) ejection fraction is one of the most important measures in cardiology and part of every cardiac imaging evaluation as it is recognized as one of the strongest predictors of outcome [1]. It allows to assess the effect of established or novel treatments [2], and it is crucial for decision making [3] e.g. to start [4] or stop [5] specific drug treatments or to implant devices [6]. CMR is generally accepted as the gold standard method to yield most accurate measures of LV ejection fraction and LV volumes. This capability and the additional value of CMR to characterize pathological myocardial tissue was the basis to assign a class 1 indication for patients with known or suspected heart failure to undergo CMR in the new Heart Failure Guidelines of the European Society of Cardiology [4].

The evaluation of LV volumes and LV ejection fraction are based on well-defined protocols [7] and it involves the acquisition of a stack of LV short axis cine images from which volumes are calculated by applying Simpson’s rule. These stacks are typically acquired in multiple breath-holds. Quality criteria [8] for these functional images are available and are implemented e.g. for the quality assessment within the European CMR registry which currently holds approximately 13,000 patients and connects 59 centers [9].

Recently, compressed sensing (CS) techniques emerged as a means to considerably accelerate data acquisition without compromising significantly image quality. CS has three requirements:

1) transform sparsity,
2) incoherence of undersampling artifacts, and
3) nonlinear reconstruction (for details, see below).

Based on these prerequisites, a CS approach for the acquisition of cardiac cine images was developed and tested [7]. In particular, the potential to acquire several slices covering the heart in different orientations within a single breath-hold would allow to apply model-based analysis tools which theoretically could improve the motion assessment at the base of the heart, where considerable through-plane motion on short axis slices can introduce substantial errors in LV volume and LV ejection fraction calculations. Conversely, with a multi-breath-hold approach, there are typically small differences in breath-hold positions which can introduce errors in volume and function calculations. The pulse sequence tested here allows for the acquisition of 7 cine slices within 14 heartbeats with an excellent temporal and spatial resolution. Such a pulse sequence would also offer the advantage to obtain functional information in at least a single plane in patients unable to hold their breath for several heartbeats or in patients with frequent extrasystoles or atrial fibrillation. However, it should be mentioned that accurate quantitative measures of LV volumes and function cannot be obtained in highly arrhythmic hearts or in atrial fibrillation, as under such conditions volumes and ejection fraction change from beat to beat due to variable filling conditions. Nevertheless, rough estimates of LV volumes and function would still be desirable in arrhythmic patients.

In a group of healthy volunteers and patients with different LV pathologies, the novel single-breath-hold CS cine approach was compared with the standard multi-breath-hold cine technique with respect to measure LV volumes and Ejection fraction. The CV_sparse work-in-progress (WIP) The CV_sparse WIP package implements sparse, incoherent sampling and iterative reconstruction for cardiac applications. This method in principle allows for high acceleration factors which enable triggered 2D real-time cine CMR while preserving high spatial and/or temporal resolution of conventional cine acquisitions. Compressed sensing methods exploit the potential of image compression during the acquisition of raw input data. Three components [10] are crucial for the concept of compressed sensing to work

I. Sparsity: In order to guarantee compressibility of the input data, sparsity must be present in a specific transform domain. Sparsity can be computed e.g. by calculating differences between neighboring pixels or by calculating finite differences in angiograms which then detect primarily vessel contours which typically represent a few percent of the...
WIP CV_sparse Sequence

The current CV_sparse sequence [12] realizes incoherent sampling by initially distributing the readouts pseudo-randomly on the Cartesian grid in k-space. In addition, for cine-CMR imaging, a pseudo-random offset is applied from frame-to-frame which results in an incoherent temporal jitter. Finally, a variable sampling density in k-space stabilizes the iterative reconstruction. To avoid eddy current effects for balanced steady-state free precession (bSSFP) acquisitions, pairing [13] can also be applied. Thus, the tested CV_sparse sequence is characterized by sparse, incoherent sampling in space and time, non-linear iterative reconstruction integrating SENSE, and LT wavelet regularization in the phase encoding direction and/or the temporal dimension. With regard to reconstruction, the ICG sequence runs a non-linear iterative reconstruction with k-space regularization in space and time specifically modified for compressed sensing. The algorithm derives from a parallel imaging type reconstruction which takes coil sensitivity maps into account, thus suppressing predominantly high acceleration factors. For cine CMR, no additional reference scans are needed because – similar to TPAI – the coil sensitivity maps are calculated from the temporal average of the input data in a central region of k-space consisting of not more than 48 reference lines. The extensive calculations for image reconstruction typically running 80 iterations are performed online on all CPUs on the MARS computer in parallel, in order to reduce reconstruction times.

Volunteer and Patient Studies

In order to obtain insight into the image quality of single-breath-hold multi-slice cine CMR images acquired with the compressed sensing (CS) approach, we studied a group of healthy volunteers and a patient group with different pathologies of the left ventricle. In addition to the evaluation of image quality, the robustness and the precision of the CS approach for LV volumes and LV ejection fraction was also assessed in comparison with a standard high-resolution cine CMR approach. All CMR examinations were performed on a 1.5 T MAGNETOM Aera (Siemens Healthcare, Erlangen, Germany). The imaging protocol consisted of a set of cardiac localizers followed by the acquisition of a stack of conventional short-axis SSFP cine images covering the entire LV with a spatial and temporal resolution of 1.2 x 1.6 mm², and approximately 40 ms, respectively (slice thickness: 8 mm gap between slices: 2 mm). LV 2-chamber, 3-chamber, and 4-chamber long-axis acquisitions were obtained for image quality assessment but were not used for LV volume quantifications. As a next step, to test the new CS-based technique, slice orientation were planned to cover the LV with 4 short-axis slices distributed evenly over the LV long axis complemented by 3 long-axis slices (i.e. a 2-chamber, 3-chamber, and 4-chamber slice) (Fig. 1). These 7 slices were then acquired in a single breath-hold maneuver lasting 14 heart beats (i.e. 2 heart beats per slice) resulting in an acceleration factor of 11.0 with a temporal and spatial resolution of 30 ms and 1.5 x 1.5 mm², respectively (slice thickness: 6 mm). As the reconstruction algorithm is susceptible to aliasing in the phase-encoding direction, the 7 slices were first acquired with a non-cine acquisition to check for correct phase-encoding directions and, if needed, to adjust the field-of-view to avoid fold-over artifacts. After confirmation of correct imaging parameters, the 7-slice single-breath-hold cine CS-acquisition was performed. In order to obtain a reference for the LV volume measurements, a phase-contract flow measurement in the ascending aorta was performed to be compared with the LV stroke volumes calculated from the standard and CS cine data. The conventional stack of cine SSFP images was analyzed by the Argus software (Siemens AG, Germany). Such software is based on an LV model and, with relatively few operator interactions, the contours for the LV endocardium and epicardium are generated by the analysis tool. Of note, this 4D analysis tool automatically tracks the 3-dimensional motion of the mitral annulus throughout the cardiac cycle which allows for an accurate volume calculation particularly at the base of the heart.

Results and discussion

Image quality – robustness of the technique

Overall, a very good image quality of the single-breath-hold multi-slice CS acquisitions was obtained in the 12 volunteers and 14 patient studies. All CS data sets were of adequate quality to undergo 4D analysis. Small structures such as trabeculations were visualized in the CS data sets as shown in Figures 3 and 4. However, very small structures, detectable by the conventional cine acquisitions, were less well discernible by the CS images. Therefore, it should be mentioned here, that this accelerated single-breath-hold CS approach would be adequate for functional measurements, i.e. LV ejection fraction assessment (see also results below), whereas assessment of small structures as present in many cardiomyopathies is more reliable when performed on conventional cine images. Temporal resolution of the new technique appears adequate to even detect visually the dysynchronous contraction pattern in left bundle branch block. Also, the image contrast between the LV myocardium and the blood pool was high on the CS images allowing for an easy assessment of the LV motion pattern. As a result, the single-breath-hold cine approach permits to reconstruct the LV 3D space with high temporal resolution as illustrated in Figure 5. Since these data allow to correctly identify the 3D motion of the base of the heart during the cardiac cycle, the LV stroke volume appears to be measurable by the CS approach with higher accuracy than with the conventional multi-breath-hold approach (see results below). With an accurate measurement of the LV stroke volume, the quantification of a mitral insufficiency should theoretically benefit (when calculating mitral regurgitant volume as ‘LV stroke volume minus aortic forward flow volume’). As a current limitation of the CS approach, its susceptibility for fold-over artifacts should be mentioned (Figs. 6A). Therefore, the field-of-view must cover the entire anatomy and thus, some penalty in spatial resolution
solution may occur in relation to the patient’s anatomy. In addition, the sparsity in the temporal domain may be limited in anatomical regions of very high flow, and therefore, in some acquisitions, flow-related artifacts occurred in the phase-encoding direction during systole (Figs. 6B, C). Also, in its current version, the sequence is prospective, thus it does not cover the very last phases of the cardiac cycle and the reconstruction may occur in relation to the plan next steps of a CMR examination. 

Performance of the single-breath-hold CS approach in comparison with the standard multi-breath-hold cine approach

From a quantitative point-of-view, the accurate and reliable measurement of LV volumes and function is crucial as many therapeutic decisions directly depend on these measures [3–6]. In this current relatively small study group, LV end-diastolic and end-systolic volumes measured by the single-breath-hold CS approach were comparable with those calculated from the standard multi-breath-hold cine SSFP approach. LVEDV and LVESV differed by 10 ml ± 17 ml and 2 ml ± 12 ml, respectively. Most importantly, LV ejection fraction differed by only 1.3 ± 4.7% (50.6% vs 49.3%) for multi-breath-hold and single-breath-hold, respectively, p = 0.77, regression: r = −0.96, p < 0.0001; y = 0.96x + 0.8 ml. Thus, it can be concluded that the single-breath-hold CS approach could potentially replace the multi-breath-hold standard technique for the assessment of LV volumes and systolic function.

What about the accuracy of the novel single-breath-hold CS technique?

To assess the accuracy of the LV volume measurements, LV stroke volume was compared with the LV output measured in the ascending aorta with phase-contrast MR. As the flow measurements were performed distally to the coronary arteries, flow in the coronary arteries was estimated as the LV mass multiplied by 0.8 ml/min/g. An excellent agreement was found with a mean of 86.8 ml/beat for the aortic flow measurement and 91.9 ml/beat for the LV measurements derived from the single-breath-hold CS data (r = 0.93, p < 0.0001). By Bland-Altman analysis, the stroke volume approach overestimated by 5.2 ml/beat versus the reference flow measurement. For the conventional stroke volume measurements, this difference was 15.6 ml/beat (linear regression analysis vs aortic flow: r = 0.69, p < 0.01). More importantly, the CS LV stroke data were not only more precise with a smaller mean difference, the variability of the CS data vs the reference flow data was less with a standard deviation as low as 6.8 ml/beat vs 12.8 ml/beat for the standard multi-breath-hold approach (Fig. 7). Several explanations may apply for the higher accuracy of the single-breath-hold multi-slice CS approach in comparison to the conventional multi-breath-hold approach:

1) With the single-breath-hold approach, all acquired slices are correctly co-registered, i.e. they are correctly aligned in space, a prerequisite for the 4D-analysis tool to work properly.

2) This 4D-analysis tool allows for an accurate tracking of the mitral valve plane motion during the cardiac cycle as shown in Figure 5, which is important as the cross-sectional area of the heart at its base is large and thus, inaccurate slice positioning at the base of a coronary artery is less critical compared to the apex.

3) Peri- and endocardial borders are tracked directly in each slice, allowing an independent tracking of individual coronary arteries. Flow in the coronary arteries was estimated as the LV mass multiplied by 0.8 ml/beat. For the CS data, this resulted in a mean difference of 15.6 ml/beat with a standard deviation of 6.8 ml/beat, whereas the reference flow measurement overestimated by 5.2 ml/beat versus the single-breath-hold CS approach. An excellent agreement was found with a mean of 86.8 ml/beat for the aortic flow measurement and 91.9 ml/beat for the LV measurements derived from the single-breath-hold CS data (r = 0.93, p < 0.0001). By Bland-Altman analysis, the stroke volume approach overestimated by 5.2 ml/beat versus the reference flow measurement. For the conventional stroke volume measurements, this difference was 15.6 ml/beat (linear regression analysis vs aortic flow: r = 0.69, p < 0.01).
the LV blood pool contour in the end-systolic phase, are excluded from the blood pool resulting in a small overestimation of the end-diastolic volume and, thus, LV stroke volume. This explanation is likely as Van Rossum et al. demonstrated a slight underestimation of the LV mass when calculated on end-diastolic phases versus end-systolic phases, as trabeculations in end-diastole are typically excluded from the LV walls [15]. In summary, this novel very fast multi-slice cine approach for the aorta and the right ventricle is currently ongoing. Finally, these preliminary data show that compressed sensing MR acquisitions in the heart are feasible in humans and compressed sensing might be implemented for other important cardiac sequences such as fibrosis/viability imaging, i.e. late gadolinium enhancement, coronary MR angiography, or MR first-pass perfusion.

The Cardiac MR Center of the University Hospital Lausanne

The Cardiac Magnetic Resonance Center (CMRC) of the University Hospital of Lausanne (Centre Hospitalier Universitaire Vaudois, CHUV) was established in 2009. The CMR center is dedicated to high-quality clinical work-up of cardiac patients, to deliver state-of-the-art training in CMR to cardiologists and radiologists, and to pursue research. In the CMR center education is provided for two specialties while focusing on one organ system. Traditionally, radiologists have focused on using one technique for different organs, while cardiologists have concentrated on one organ and perhaps one technique. Now in the CMR center the focus is put on a combination of specialists with different background on one organ. Research at the CMR center is devoted to four major areas: the study of:

1) cardiac function and tissue characterization, specifically to better understand diastolic dysfunction,
2) the development of MR-compatible cardiac devices such as pacemakers and ICDs;
3) the utilization of hyperpolarized 13C-carbon contrast media to investigate metabolism in the heart, and
4) the development of 19F-fluorine-based CMR techniques to detect inflammation and to label and track cells non-invasively.

For the latter two topics, the CMR center established tight collaborations with the Center for Biomedical Imaging (CIBM), a network around Lake Geneva that includes the École Polytechnique Fédérale de Lausanne (EPFL), and the universities and university hospitals of Lausanne and Geneva. In particular, strong collaborative links are in place with the CVMR team of Prof. Matthias Stuber, a part of the CIBM and located at the University Hospital Lausanne and with Prof. A. Comment, with whom we perform the studies on real-time metabolism based on the 13C-carbon hyperpolarization (DNP) technique. In addition, collaborative studies are ongoing with the Heart Failure and Cardiac Transplantation Unit led by Prof. R. Hullin (detection of graft rejection by tissue characterization) and the Oncology Department led by Prof. Coukos (T cell tracking by 19F-MRI in collaboration with Prof. Stuber. R. van Heeswijk, CIBM, and Prof. O. Michielin, Oncology). This structure allows for a direct interdisciplinary interaction between physicians, engineers, and basic scientists on a daily basis with the aim to enable innovative research and fast translation of these techniques from bench to bedside.

The CMRC is also the center of competence for the quality assessment of the European CMR registry which holds currently approximately 33,000 patient studies acquired in 59 centers across Europe.

The members of the CMRC team are: Prof. J. Schwitter (director of the center), PD Dr. X. Jeannenaud, Dr. D. Locca, MER, Dr. P. Monney, Dr. T. Rutz, Dr. C. Sierro, and Dr. S. Koestner (cardiologists, staff members).

LV short-axis slice: CV_SPARSE

Oversaturation of end-diastolic LV volumes by volumetric measurements. In comparison to ejected blood from the LV as measured with phase-contrast techniques, the volumetric measurements of LV stroke volume overestimated by approximately 5 ml, most likely by oversaturation of LV end-diastolic volume. Small trabeculations (yellow contours in BA) are included into the LV blood volume (red contour in BA) in diastole, while these trabeculations (yellow contours in BB) are typically included in the end-diastolic phase (red contours in BB). For the same reasons, LV mass (green contour minus red contour) is often slightly underestimated in diastole vs systole.

LV short-axis slice: CV_SPARSE

The authors would like to thank all the members of the team of MR technologists at the CHUV for their highly valuable participation, helpfulness and support during the daily clinical CMR examinations and with the research protocols. Finally, a very important acknowledgment goes to Dr. Michael Zenge, Ms. Michaela Schmidt (affiliated cardiologist), Dr. G.L. Fetz (radiologist in training, rotation), PD. Dr. S. Muzzarelli (affiliated cardiologist), Prof. C. Beigelman (cardiologist, rotation), Dr. M. Zenge (research protocol coordinator), Dr. G.L. Fetz (radiologist in training, rotation), PD. Dr. S. Muzzarelli (affiliated cardiologist), and the members of the team of MR technicians.

References

As outlined by Liu et al. in [1], the image reconstruction can be formulated as an unconstrained optimization problem. In the current implementation, this optimization is solved using a Nesterov-type algorithm [7]. The L1-regularization with a redundant Haar transform is efficiently solved using a Dykstra-type algorithm [8]. This allowed a smooth integration into the current MAGNETOM platform and, therefore, facilitates a broad clinical evaluation.

Materials and methods

Nine healthy human volunteers (57.4 male/56.7 female) and 20 patients (54.4 male/40.0 female) with suspected cardiac disease were scanned on a 1.5T MAGNETOM Aera system under an approved institutional review board protocol. All nine volunteers and 16 patients were imaged using segmented cine TrueFISP sequences with conventional GRAPPA factor 2 acceleration (conventional iPAT 2), T-PAT factor 4 acceleration (conventional T-PAT 4), and T-PAT factor 4 acceleration with iterative k-t-sparse SENSE reconstruction (iterative T-PAT 4). The remaining 4 patients were scanned using only conventional iPAT 2 and iterative T-PAT 4 techniques. Note that the iterative technique is fully integrated into the standard reconstruction environment.

The imaging parameters for each imaging sequence are provided in Table 1. All three sequences were run with basal septal hypertrophy. In both series, the conventional iPAT 2 and iterative T-PAT 4 techniques produced slightly lower EF values compared to the other techniques, although this was not found to be statistically significant. The iterative reconstruction provided comparable image quality, noise, and artifact scores to the conventional reconstruction using iPAT 2. The conventional T-PAT 4 technique had lower image quality and higher noise scores compared to the other two techniques. The iterative T-PAT 4 segmented cine technique allows for greater than 50% reduction in acquisition time for comparable image quality and spatial resolution as the clinically used iPAT 2 cine TrueFISP technique. This iterative technique could be extended to permit complete heart coverage in a single breath-hold thus greatly simplifying and shortening routine clinical cardiac MRI protocols, which has been one of the biggest obstacles to wide acceptance of cardiac MRI. With a shorter cine acquisition, additional advanced imaging techniques, such as perfusion and flow, can be more readily added to patient scans within a reasonable protocol length.
There are currently some limitations to the technique. Firstly, the use ofSENSE implies that aliasing artifacts can occur if the field-of-view is smaller than the subject, which is sometimes difficult to avoid in the short axis orientation. But a solution to this is promised to be part of a future release of the current prototype. Secondly, the image reconstruction times of the current implementation seem to be prohibitive for routine clinical use. However, we anticipate future algorithmic improvements with increased computational power to reduce the reconstruction time to clinically acceptable values.

With sufficiently high acceleration, the technique can also be used effectively for real time cine cardiac imaging in patients with breath-holding difficulties or arrhythmia. Figure 6 shows that real-time acquisition with T-PAT 6 and k-t iterative reconstruction still results in excellent image quality.

In conclusion, cine TrueFISP of the heart with inline k-t-sparse iterative reconstruction is a promising technique for obtaining high quality cine images at a fraction of the scan time compared to conventional techniques.

Mustafa R. Bashir, M.D., is an Assistant Professor of Radiology at Duke University Medical Center, Durham, USA. He joined the faculty at Duke in 2010, and serves as the Director of MRI and Director of Body MRI. In 2012, he was named the Medical Director of the Center for Automated Magnetic Resonance Development, Duke Radiology’s MRI research and development facility. He has been awarded several industry research grants as principal investigator and serves as sole imaging principal investigator on several NIH-funded grants. Dr. Bashir serves as a working group chair for the First Imaging Department Data System (GL-RADS) committee for the American College of Radiology and is a senior radiologist for the National Alcoholic Steatohepatitis Clinical Research Network. His clinical and research interests include abdomen MRI, free imaging, quantitative imaging, and novel contrast mechanisms.

The theme of the 99th Annual Meeting of the Radiological Society of North America is “The Power of Partnership.” Nowhere is this concept better exemplified than in the cooperation between academic medical centers and industry partners in the development and improvement of diagnostic imaging. This issue of MAGNETOM Flash contains a wealth of examples of how such collaborations have advanced the discipline of MRI.

As the world’s population’s healthcare needs grow, so must diagnosis and disease management continue to advance. Diagnostic imaging plays an increasingly central role in detecting and characterizing disease, and guiding therapy. In particular, MRI remains a cornerstone of neuroscience, orthopedic, oncologic, and cardiovascular imaging. MRI has both real advantages in leveraging useful contrast mechanisms for visualization of anatomy and pathology. This is well-demonstrated in articles, such as the one by Mustafa Bashir, M.D., and quantitative myocardial relaxation mapping (Moon et al. page 104).

Page 108 and 117: Such techniques are shown to provide high resolution, multiplanar acquisitions in single breath-holds, which can both shorten total examination time and provide comparable or more accurate measurements of left ventricular ejection fraction and stroke volume, compared with conventional methods.

The broad availability of commercial wide-bore systems with high channel densities makes a clinical MRI a reality in a larger portion of the population. In their article on the New York University-Langone Medical Center experience using Radial VIBE*, Tobias Bloch et al. show the power of a motion-robust non-Cartesian strategy to obtain free-breathing, artifact-free, volumetric T2-weighted images in the body (page 6). Such paradigms can be applied to improve image quality in patients unable to hold their breath, and to enhance the MRI experience by providing healthier patients with a more comfortable examination with fewer breath-holds. In addition, colleagues at the University Hospital of Lausanne and Northwestern University demonstrate the feasibility of rapid cardiac acquisition using compressed sensing methods (page 108 and 117). Such techniques are shown to provide high resolution, multiplanar acquisitions in single breath-holds, which can both shorten total examination time and provide comparable or more accurate measurements of left ventricular ejection fraction and stroke volume, compared with conventional methods.
